speech disfluency as compared to the other two groups (Suh et al. 2014). On a measure of auditory perceptual skills, the HFA group showed heightened pitch discrimination than both the OO and TD groups; the abilities of the OO did not differ from the TD group (Eigsti and Fein 2013). The ability to organize semantic categories was compared across the groups and revealed that both the OO and HFA groups were less consistent in acquiring and using category structures than the TD group, which may be related to with an underlying difficulty with generalization observed among individuals with ASD (Naigles et al. 2013). Scores on a verbal memory measure were similar across the OO and TD groups. The HFA group's overall score on the verbal memory measure was solidly average; however, more participants in this group received below average scores than in the other two groups (Tyson et al. 2014).

The academic functioning of the OO group fell in the average range, and the TD and OO group scored similarly across all measures of reading, mathematics, and writing. The HFA group also scored in the average range across academic domains, but scored significantly lower on subtests of reading comprehension and mathematical problem solving than the OO group. These findings indicated that the academic abilities of individuals who achieved OOs are similar to those of their typically developing peers, even in areas where individuals who have retained their ASD diagnoses exhibit some ongoing difficulty (Troyb et al. 2014a).

When directly assessed, executive functioning fell in the average range across the three groups, but the OO and HFA groups exhibited more impulsivity and less efficient planning and problem solving than the TD group. Parent report of everyday use of executive functioning revealed average abilities in both the OO and TD groups; however, the OO group exhibited more difficulty than the TD group on set shifting and working memory. Participants in the HFA group demonstrated more difficulty on all parent-reported executive functioning domains, with a clinically significant weakness in attention shifting (Troyb et al. 2014c).

An exploration of psychiatric functioning revealed higher rates of ADHD and specific phobias in the HFA and OO groups, as compared to the TD group. The OO and HFA groups were also more likely to meet diagnostic criteria for tic disorders. However, tics appeared to abate over time more frequently in the OO group as compared to the HFA group, and by the time of the study, tic disorders were no more prevalent in the OO group than in the TD group. The HFA group had the highest level of comorbid psychiatric symptoms both at the time of testing and earlier in their development (Orinstein et al. under 2015b).

Parent report of intervention histories of the OO and HFA groups was collected and examined. Results indicated that parents of participants in the OO group had earlier concerns about their child's development and received earlier referrals to specialists than did parents of participants in the HFA group. On average, the OO group received earlier and more intensive intervention than the HFA group, with more OO participants receiving applied behavior analysis. Children in the HFA group were more likely to have received medication, especially antipsychotics and antidepressants (Orinstein et al. 2014).

In 2014, Anderson et al. published a prospective study examining the range of outcomes among young adults with ASD, and their sample included eight participants who achieved a "very positive outcome." These eight individuals were diagnosed with ASD at age 2, were reevaluated at 3 years of age, and no longer met diagnostic criteria for ASD when they were seen for the third evaluation when they were 19 years old. At the age of 2 years, participants who achieved very positive outcomes showed similar degrees of repetitive behaviors, social delays, and adaptive functioning delays as did high-functioning participants who retained their ASD diagnoses. Participants who achieved a very positive outcome were also more likely to participate in individual treatment by age 3 and displayed a greater reduction in repetitive behaviors between the ages of 2 and 3 years than did other high-functioning participants in the sample who retained their ASD diagnoses. At the age of

19, participants in the very positive outcome group exhibited fewer symptoms of ASD in the socialization, communication, and repetitive behavior domains and had average verbal reasoning and academic abilities, as compared to high-functioning participants who retained their ASD diagnosis. In addition, participants in the very positive outcome group were also less likely to present with symptoms of irritability, hyperactivity, or depression. At the age of 19, of the eight participants, five were living away from home, seven were enrolled in college, five were employed, and none were taking psychotropic medication.

Future Directions

Questions that remain about optimal outcomes in ASD include how many children with ASD have the capacity to achieve these outcomes and what early factors predict these outcomes. A key question is what genetic or other biological factors mark the children who have the potential to achieve optimal outcome, even if this outcome is dependent of intense early intervention. Future prospective intervention studies should explore types of intervention to determine which is most likely to result in OOs following an ASD diagnosis. These studies would benefit from gathering data about fidelity with which intervention is delivered. In addition, future prospective studies should include frequent assessment intervals in order to explore the nature and timing of symptom reduction.

Another important question that remains unanswered is to what extent neurological characteristics have normalized in children who achieved OOs. Studies using structural and functional neuroimaging could help determine to what extent the neuroanatomical structures, functioning, and pathways have normalized in this population. Future research should also examine social functioning in more detail among individuals who achieved OO and specifically investigate peer interactions and the quality of friendships in order to determine whether subtle residual social deficits exist in this group.

Redirection

Rebecca DeAquair

The Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Redirection is the process of shifting one's focus or actions from one activity to another. As a guidance technique most often used to interrupt behavior, it orients an individual from one behavior or stimulus to another and acts to elicit the desired behavior or outcome. Redirections can occur in

subtle ways such as a change in topic within a conversation or the presentation of an instructional material or in a more intrusive manner such as physically positioning oneself between the individual and a certain item or location or by physically interrupting stereotypy and reengaging in the task at hand.

Reduced Prioritization of Facial Threat in ASD

Noah J. Sasson
The University of Texas at Dallas, Richardson,
TX, USA

Synonyms

Threat detection; Threat perception; Threat superiority

Definition

Threat perception involves the rapid detection of potentially harmful stimuli within the environment. Typically developing (TD) individuals demonstrate a robust “threat superiority effect,” in which they detect threatening stimuli amongst nonthreatening stimuli faster and with greater

accuracy than vice versa (for a review, see LoBue and Rakison 2013). The prioritization of threatening stimuli is adaptive, facilitates biological readiness and self-protection, and occurs for dangers that are both ancient (e.g., snakes) and more modern (e.g., guns). People, of course, can also be a source of threat and not surprisingly threatening emotional expressions such as anger, and even threatening faces lacking emotion like those that are hypermasculine and perceived as aggressive (Shasteen et al. 2015) are detected more quickly and with more accuracy by TD individuals than are nonthreatening faces (Pinkham et al. 2010).

Autism spectrum disorder (ASD) is characterized by difficulties in social understanding, with many but not all on the spectrum exhibiting reduced abilities in face processing, emotion recognition, and mentalizing skill. A recent study examined whether these difficulties extend into the domain of social threat detection (Sasson et al. 2016). A failure by autistic adults to demonstrate a classic threat superiority effect for angry emotional expressions could indicate a reduced sensitivity to facial threat signals that could contribute to social misunderstanding, miscommunication, and under certain circumstances, increased susceptibility for victimization.

Sasson et al. (2016) compared performance between 21 autistic adults without intellectual disability and 28 TD controls on a “face in the crowd” task in which participants determine whether all faces within a 3×3 matrix are displaying the same emotional expression or whether one of the faces in the crowd is displaying a discrepant emotion. Unlike previous tests of the threat superiority effect in ASD, the task used here included veridical facial photographs and was constructed to mimic a true “crowd effect” by ensuring that no individual was presented twice within the same matrix. Results for TD participants replicated previous findings: they detected angry faces more rapidly than happy faces, both within crowds of happy distractor faces and neutral distractor faces. In contrast, autistic adults did not share this pattern, showing no response time advantage for detecting angry face targets relative to happy and neutral face targets. Furthermore,

whereas TD participants took longer to respond on “target absent” trials in which all faces in the crowd were angry compared to all happy or all neutral, autistic participants did not. This suggests that angry faces disproportionately captured attention for TD participants, but did not for autistic participants.

However, like TD participants, autistic adults were more accurate at detecting angry relative to happy faces. This suggests that autistic adults do assign some level of increased salience to signals of facial threat, but the lack of a concurrent response time advantage for detecting angry faces within a crowd – the finding that typically defines the presence of a threat superiority effect – suggests that autistic adults are characterized by a reduction in the adaptive prioritization of social threatening information. As such, this finding may reflect an additional domain in which social cognitive differences in autism relate to broader aspects of their social disability. Autistic adults are often more trusting, can be more vulnerable to manipulation, and experience high rates of victimization (Weiss and Fardella 2018). Whether the reduced prioritization of facial threat found in this study might relate to increased vulnerability for social harm is currently unclear. It is also unclear whether autistic adults would demonstrate a similar reduction in the “threat superiority effect” for sources of nonsocial threat (e.g., guns). If so, the findings here might reflect more general perceptual differences rather than a specific difficulty assessing aspects of social threat. If, however, autistic adults demonstrate an intact “threat superiority effect” for nonsocial stimuli, the discrepancy in threat assessment between social and nonsocial threat would parallel other aspects of the condition in which social cognitive difficulties are often dissociable from general cognitive ability.

Refrigerator Mother

Victoria Shea
Department of Psychiatry, TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

The term “refrigerator mother,” although commonly attributed to Bruno Bettelheim, appears to

derive instead from the following section of a 1949 paper by Leo Kanner: “Most of the patients were exposed from the beginning to parental coldness, obsessiveness, and a mechanical type of attention to material needs only. They were the objects of observation and experiment conducted with an eye on fractional performance rather than with genuine warmth and enjoyment. They were kept neatly *in refrigerators* [emphasis added] which did not defrost.”

Regional Centers

Peter Doehring
Foundations Behavioral Health, Doylestown,
PA, USA
ASD Roadmap, Chadds Ford, PA, USA

Definition

Centers that develop or provide service or training related to Autism Spectrum Disorder or ASD to a county or multicounty region. We distinguish regional centers from centers serving an area smaller than a county (e.g., a city or school district), and from other centers serving a larger area (e.g., a statewide programs).

Most regional centers are, at least partially, publicly funded. They are often formally mandated to serve a geographically defined area (e.g., a county or multicounty region), and a

subset of the overall population, as defined by age (e.g., between 3 and 21 years of age), or other characteristics of the person (e.g., those with ASD and significant intellectual disability or ID), or defined by a specific range of services provided (e.g., early intervention, behavioral health, vocational training, etc.). This mandate is usually dictated by the funding source. For example, many states allocate public funding for early intervention (Birth to 3) and behavioral health services by county, and may administer these services directly via a county-level program or contract out these services privately. Some of these centers were originally established when the institutionalization of persons with significant intellectual disabilities or psychiatric disorders was the standard of practice. As is the case of statewide service programs, regional centers providing direct service have been on the decline since the mid-1970s, with the increased emphasis on community-based educational and psychiatric services, and increased number of persons identified with ASD.

Some centers emerged because the designated population or need was too small to offer services locally. For example, individual school districts may not have enough students with ASD to create an ASD-specific program, but districts across a county may together designate a specific school district or another entity to operate a specialized program.

Other programs serve some of the functions of regional centers: University-based centers of excellence on developmental disabilities may assume regional leadership for training, specialized children’s hospital may develop satellite programs to extend services throughout a broader area, or private ASD centers serve as a hub for a range of services across a region (Handelman and Harris 2001, 2006). Such centers often have greater flexibility to develop new programs to fill critical gaps, and are not as vulnerable to the year-to-year fluctuations in levels of state and federal funding. Such centers are not held legally accountable, however, if they are not accessible to the entire population or fail to deliver critical services in a timely manner.

Register Variation

Megan Lyons
Laboratory of Developmental Communication Disorders, Yale Social and Affective Neurodevelopment of Autism Program, Yale Child Study Center, New Haven, CT, USA

Synonyms

[Inflection](#); [Language style](#); [Language variation](#)

Definition

Register variation includes the ability to vary one's language style based on the social context or communication partner. For example, adult speakers talk differently to babies than they do to other adults. Individuals with ASD often have difficulty with register shifts, using the same style of speech or vocabulary across communication partners regardless of age (e.g., same-aged peers vs. adults), status (peer vs. teacher), or context (home vs. work). Individuals with ASD also experience difficulty using register shifts flexibly to make requests in different contexts (e.g., favor vs. a right) or to persuade.

Registered Behavior Technician (Definition)

Solandy Forte
The Center for Children with Special Needs, Glastonbury, CT, USA
Milestones Behavioral Services, Inc., Milford, CT, USA

In the last few decades, there has been a significant increase in the prevalence of autism spectrum disorder (ASD). Today, 1 in 68 children is diagnosed with ASD (Centers for Disease Control and Prevention 2016) resulting in an increase in the demand of interventions that are evidence-based and shown to be effective in treating the symptoms of the disorder, therefore, leading to an increase in the demand of services based on the principles of applied behavior analysis (ABA). Behavioral interventions derived from these principles have been identified to be effective and efficient in improving the symptoms of ASD as well as teaching critical and socially significant skills to the consumers of this treatment (Myers and Johnson 2007; Howard et al. 2005; Eikeseth et al. 2007; Lovaas 1987). The increase in the demand of ABA services has also resulted an increase in the need for individuals who are adequately trained and qualified to implement the ABA interventions to the vulnerable population of individuals they serve (Hughes and Shook 2007).

In order to meet the need for qualified implementers of ABA, the Behavior Analysis

Certification Board (BACB[®]) responded by establishing the Registered Behavior Technician (RBT[®]) credential in 2014 for non-certified individuals (e.g., paraprofessionals and direct-care staff) that requires these individuals to complete specific training in the implementation of behavioral technology and meet other requirements established to obtain the credential. The training is to be delivered under the supervision of a Board Certified Behavior Analyst (BCBA[®]) and must adhere to the requirements established by the BACB. The RBT requirements established by the BACB include the following:

- (a) Be at least 18 years of age
- (b) Complete and pass a criminal background check
- (c) Have obtained a minimum of a high school diploma
- (d) Complete a 40-h, combined didactic and experiential training program that is aligned with the RBT task list
- (e) Pass a competency checklist (demonstrate the ability to implement behavioral interventions and tasks in a role-play or in vivo format) as evaluated by the trainer
- (f) Pass the RBT examination
- (g) Pay all of the fees associated with the RBT credentialing process (Forte et al. 2018)

The 40-h combined didactic and experiential training includes a review and demonstration of behavioral interventions commonly implemented by behavior technicians such as reinforcement, prompting, discrete trial teaching, task analysis, shaping, and data collection, to name a few. The BCBA delivering the training is responsible for developing the didactic training content (e.g., PowerPoint slides, worksheets, visuals) and experiential activities (e.g., role-play or in vivo training opportunities). Again, all training targets must be aligned with the 20-item RBT task list. Once the trainees have completed the 40-h training program, they must also complete a competency assessment that evaluates their performance when demonstrating behavioral interventions based on the RBT task list. The task list includes common tasks completed by RBTs and falls under

the categories of “Measurement, Assessment, Skill Acquisition, Behavior Reduction, Documenting and Reporting, and Professional Conduct and Scope of Practice” (BACB 2014, p. 1). The trainee is responsible for submitting verification indicating that they have completed all the necessary requirements in order to receive approval for taking the examination administered through the BACB.

To maintain the RBT credential, the individual must be supervised for a minimum of 5% of the hours they have implemented ABA interventions per month. For example, an RBT must receive at least 1.5 h of supervision for every 30 h they have engaged in the implementation of ABA interventions. The BACB has set up these requirements in order to ensure that the delivery of high-quality ABA services is implemented with integrity and it will have a direct impact on the consumers of ABA. At this time, the requirements do not require continuing education to maintain the credential. However, the BACB[®] has established a group of subject matter experts (SMEs) whose task is to evaluate the requirements of the RBT overtime (approximately every 5 years) and make revisions to the requirements based on research evaluating the efficacy of the training requirements. Further, the RBT credential is a relatively new credential, and the SMEs are continuing to work on *operationalizing* the task list items so that they can be appropriately measured by supervisors conducting the competency assessments (Carr et al. 2017).

- acquired and subsequently lost for at least a period of 3 months. Regression in ASD has been relatively poorly defined and has mainly been studied using retrospective parental reports after the individual has received an autism spectrum disorder (ASD) diagnosis. In her review, Rogers defined autistic regression as “loss of previously acquired language and social relatedness skills during the first 3 years of life” (Rogers 2004). Parr et al. (2011) recently used the term “early developmental regression” in the study of regression before age 3 years. In ASD, the most commonly reported regression is the loss of use of words or phrases, or developing language. Non-language regression (e.g., loss of sociability, loss of interest in play) is less clearly defined and may be difficult to distinguish from the recognition of onset of symptoms of ASD or variation in behavior and skills in ASD. Other regression (e.g., loss of motor skills) requires consideration of other diagnoses (see ► [“Rett Syndrome”](#) and ► [Childhood Disintegrative Disorder](#)).

Regression

Definition

Regression is the loss of previously acquired skills. In a developmental context, a child is considered to have regressed when there is evidence that he/she has lost a definitely acquired skill that was previously used regularly for some time. The Autism Diagnostic Interview-Revised (ADI-R) requires skills previously

Historical Background

Early research about regression focused on word loss, timing, and the potential association with seizures and epilepsy (Kurita 1985; Tuchman et al. 1991). The subsequent link between the MMR vaccination, ASD, and regression led to considerable interest from researchers, both in terms of understanding regression better and investigating the possible link with MMR and other environmental factors (e.g., thimerosal). Investigating regression through retrospective reports has long been a methodological weakness in research methods. To date, most published research findings have used the ADI-R to characterize parental accounts of regression. Home videos have confirmed the reality of developmental regression in young children with ASD (Werner and Dawson 2005). However, the longitudinal prospective study of infants at increased risk (such as the younger siblings of children with ASD) is likely to shed most light on the process of

regression, both from a behavioral and neurobiological perspective (Landa et al. 2007; Werner et al. 2005).

Current Knowledge

Regression occurs in approximately 20–30% of children with ASD and is seen at equal rates in males and females with ASD. Early developmental regression is defined as onset before age 3 years, and onset is most often reported between 18 and 24 months of age. Some children over age 3 years have been reported to lose language, and nonlanguage skills (Parr et al. 2011). Regression occurs as frequently in families with one child with ASD (singleton) as families with two or more affected children (multiplex) (Parr et al. 2011), suggesting no genetic or familial basis to regression (Parr et al. 2008, 2011).

Developmentally, and in the general pediatric population, regression of skills is uncommon and suggests that some form of severe process is occurring in the brain. For example, children with early-onset epilepsy lose acquired skills and usually enter a period of developmental stasis, in which new skill acquisition stalls. One such condition is Landau-Kleffner syndrome – following typical development, children develop seizures, lose expressive language, and seem to have difficulties with understanding; other behavioral difficulties and cognitive impairments co-occur. An electroencephalogram (EEG) is abnormal.

Regression in ASD should be differentiated from Rett syndrome (a pervasive developmental disorder but not an ASD). Rett syndrome is seen in girls and very occasionally in boys. Following a period of normal development, loss of skills occurs, followed by microcephaly and the onset of seizures and other features (classically hand wringing, a sighing respiratory pattern, and scoliosis). The Rett phenotype is differentiated from regression in ASD through the clinical history and examination and, when necessary, genetic testing (for the MECP2 or CDLK5 mutations). Very rarely, a catastrophic regression of all skills is seen in children who have developed typically for at least the first 2 years. This presentation

may be a manifestation of childhood disintegrative disorder (CDD, formerly known as Heller syndrome) – children require investigation, but in CDD, no abnormality is found on laboratory testing or through EEG or cranial imaging.

Clinically, parents' descriptions of regression should always be taken seriously, and a search for a cause of regression made through history taking, examination, and investigations if necessary. While regression may be a presenting feature of ASD, often parents have already been concerned about their child's early social communication development and, in particular, the relatively slow acquisition of speech. In the clinical history, regression should be differentiated from an account of developmental skills gained and then not used for some period. This is particularly the case with word loss – children with typical development may use a word and then not use that word again for days or weeks. However, during this time, the child's language usually continues to develop – other words come and many become established (the so-called word explosion). Forward developmental progress is maintained at all times. This contrasts with the account of early regression in ASD, where parents report that their child loses the use of words and even phrases sometimes rapidly (some parents report “overnight”), or progressively over several weeks, without new language skills being gained. For all parents, any loss of their child's skills is extremely distressing. Recent data show that the loss of previously acquired speech in the early years is most frequently seen in association with ASD (Pickles et al. 2009); clinicians should specifically ask about features of ASD when regression is reported.

A regression history has usually been taken after the event. As increased knowledge is gained about the early behavioral manifestations of ASD in the first few years of life, and with new guidelines regarding ASD surveillance (Johnson et al. 2007), more contemporaneous data will become available. When seeing the parents of a child with a history of possible loss of skills, a thorough developmental history, together with a detailed account of the regression episode, including any coexisting illnesses or occurrences is required. In

particular, the presence or absence of a pre-regression ASD history should be sought. A detailed family history including relatives with ASD is required. The typical history is one of loss of skills, most commonly speech. Parents may report loss of sounds used communicatively or loss of words and phrases used with meaning. Parents may relate regression to an illness or other event such as vaccination. However, epidemiological and other studies have not identified a link between vaccinations (particularly the measles, mumps, and rubella (MMR) vaccination) (Fombonne and Chakrabarti 2001; Richler et al. 2006). Parents may also report loss of other skills, including social abilities, motor skills, and occasionally toileting skills. These problems have been much more difficult to quantify; however, any account of loss of skills in these latter areas should always lead clinicians to consider other diagnoses and possible causes. A general and neurological examination should always be undertaken. Some parents may bring video recordings of their child pre-, during, and postregression – mobile telephone videos have increased the frequency of this. This video evidence is always useful, and clinicians should invest time in watching them. Observational accounts from other settings (e.g., nursery staff) are also valuable. Based on the clinical presentation including the results of the history and physical examination, the clinician will make a judgment about whether to undertake further investigations. In the presence of neurodevelopmental history consistent with ASD, and a regression history without events of particular note, and in the absence of any noteworthy neurological findings, most clinicians do not investigate children with regression but either make an ASD diagnosis or assign the regression as “related to ASD.” However, if the regression is accompanied by a “non-ASD type” developmental history, symptoms or signs not usually seen in ASD, seizures, or abnormal findings on detailed neurological examination, investigations are required; when clinicians are not experts in ASD or pediatric neurology, onward referral to specialist services should be undertaken.

Parr et al. (2011) recently reported on the characteristics of regression in 124 children from a sample of 458 with ASD (27%). Early

developmental regression occurred in 23% of the children who lost skills. Late regression was more likely to be nonlanguage regression or a mix of language and nonlanguage regression. Social regression was the most frequently reported non language regression concern, but parents also described regression in other areas. In Parr’s study, most children with regression regained the skills they had lost and subsequently make developmental progress – the mean time from loss to skills being regained was 20 months. A small proportion of children with ASD and regression were reported by their parents to either experience a prolonged developmental plateau or not regain their skills for at least 2 years – these children had more evidence of developmental impairment than children who regained skills. In recent years, a number of studies have identified that language and cognitive outcomes are less good and that some autism symptoms are more severe in children with ASD who experience regression, compared with children with ASD with no history of regression (Baird et al. 2008; Parr et al. 2011). Data show that children with regression have a greater degree of social impairment (as measured by their ADI-R social domain score) and lower IQ scores and adaptive behavior scores. It is not yet known whether the long-term outcome differs for ASD children who lose skills, compared with those without regression.

While there are a lot of data showing what does not lead to regression, the cause of regression remains unknown. Lainhart et al. (2002) reported that regression was as common in families with the broader autism phenotype (BAP), as in those without the BAP, suggesting regression did not have a familial cause (a finding consistent with those of Parr et al. 2011). There were some early genetic findings of possible family association and genetic linkage, but this was not replicated by Parr and the International Molecular Genetic Study of Autism Consortium (Parr et al. 2006).

Treatment

When a medical cause of regression is found (e.g., an epileptic encephalopathy), this should be treated by a clinician with expertise in pediatric neurology. For most young children with ASD, the symptom profile in early development can be

very varied and although there is no evidence base for any specific treatment for regression, this presentation should inform the needs and skills based management plan (early intervention) for the child and family. Whether or not specific intervention aimed to improve speech and social communication alters developmental progress following regression is unknown. However, parents whose children regress and those professionals supporting the child and family should be encouraged to continue to use appropriate strategies to improve the child's social communication and monitor progress. Clinicians and community support staff should pay careful attention to the needs of parents and other family members at this time of increased stress and uncertainty for the family.

Future Directions

Prospective studies of infant siblings born in families with a child with ASD ("high-risk" studies) will be of particular value in documenting the course of regression and subsequent progress. Intervention studies with these young children with ASD may shed light on the utility of early intervention in an attempt to improve developmental progress and outcome following regression. However, it should be noted that such prospective studies will require large sample sizes to study enough siblings who will develop ASD and go on to lose skills (Ozonoff et al. 2010); thus, collaborative research strategies will be necessary to further improve our understanding of regression. Certain aspects of regression (e.g., skill loss after age 3 years) require systematic surveillance studies including very large populations. The prospective identification and early clinical referral of children who develop regression (either early or late) would also allow detailed investigation, including imaging, neurophysiology, and genetic and other laboratory testing.

Definition

Regression analysis is a statistical tool used to model the relationship between a dependent variable and one or more independent variables. Specifically, regression analysis describes how the typical value of the dependent variable changes when any one of the independent variables increases or decreases, while holding the other independent variables constant. For example, regression analysis has been utilized to demonstrate that sensory processing dysfunction significantly influences externalizing behavior among preschool-aged children with autism (Tseng et al. 2011).

Rehabilitation Act of 1973

Oren Shtayermman

New York Institute of Technology Mental Health
Counseling, Old Westbury, NY, USA

Definition

The Rehabilitation Act of 1973 was a national strategy to improve the prospects for individuals with disabilities and ban judgment in employment against otherwise talented handicapped individuals. This Act was to substitute the Vocational Rehabilitation Act and to cover and revise the approval of awards to States for vocational rehabilitation services, with distinct weight on services to those with the most severe handicaps; to increase special Federal accountabilities and

teaching programs with respect to handicapped persons; to institute special responsibilities in the Secretary of Health, Education, and Welfare for organization of all programs with respect to handicapped individuals within the Department of Health, Education, and Welfare; and for other purposes. The Rehabilitation Act of 1973 had 11 different purposes:

1. Develop and implement complete State plans for meeting present and prospect needs for providing vocational rehabilitation services to handicapped individuals, serving first those with the most severe handicaps
2. Assess rehabilitation potential of handicapped persons
3. Conduct a study to develop approaches of providing rehabilitation services to meet the existing and forthcoming needs of handicapped persons for whom vocational aim is not likely or viable so that they may progress their capability to live with better independence and self-sufficiency
4. Help in the creation and enhancement of rehabilitation services
5. Advance novel and groundbreaking methods of applying the greatest advanced medical technology, scientific successes, and psychological and social information to resolve rehabilitation problems and develop new and innovative methods of providing rehabilitation services for handicapped persons through research, special projects, and demonstration
6. Start and enlarge services to groups of handicapped individuals who have been underserved in the past
7. Conduct many studies and tests to emphasis on long abandoned problem areas
8. Encourage and expand employment opportunities in the communal and private areas for handicapped persons and to place such individuals in employment
9. Create customer assistance pilot projects
10. Offer aid for the purpose of increasing the number of rehabilitation personnel and increasing their skills through training
11. Evaluate existing approaches to architectural and transportation barriers confronting handicapped persons and advance novel methods and solutions to current architectural and transportation barriers impeding handicapped individuals

 Institute of Technology, Central Islip, NY, USA
 Threshold Program, Lesley University,
 Cambridge, MA, USA

Synonyms

[Biomedical engineer](#)

Definition

A rehabilitative engineer is a person who applies engineering principles to develop assistive technology to aid individuals with different kinds of disabilities. Rehabilitative engineering is considered a subspecialty of biomedical engineering.

As defined by the Rehabilitation Act of 1973, amended in 1998, rehabilitative engineering is the systematic application of engineering sciences to design, develop, adapt, test, evaluate, apply, and distribute technological solutions to problems confronted by individuals with disabilities in functional areas such as mobility, communications, hearing, vision, and cognition and in the activities associated with employment, independent living, education, and integration in the community (Engineers Australia 2011).

Rehabilitative engineers are the key to the development and delivery of “assistive technology,” a term which refers to technologies and principles that meet the needs of and address the barriers confronted by individuals with disabilities in a range of life areas. Assistive technology is often associated with education, rehabilitation, employment, transportation, independent living, and recreation (Engineers Australia 2011).

Reinforcement

Sunny Kim

Koegel Autism Center, University of California, Santa Barbara, Santa Barbara, CA, USA

Synonyms

[Adding](#); [Reinforcing stimulus](#); [Strengthening](#); [Supporting](#)

Definition

Reinforcement is defined as strengthening a specific response (Skinner 1963). For example, imagine a scenario where a mother is attempting to teach her child with autism to say the word “bubble.” Every time the child attempts to say the word “bubble” on command, the mother might, strengthen the response by blowing bubbles, thus reinforcing the behavior. Moreover, reinforcement is responsible for the continued performance of the behavior that has been acquired (Skinner 1963). There are two types of reinforcement: positive reinforcement and negative reinforcement. Positive reinforcement is strengthening a behavior by rewarding an attempted response (Baltruschat et al. 2011; Fisher et al. 2005). The bubble scenario described above is an example of positive reinforcement. Negative reinforcement, on the other hand, is strengthening a behavior by removing a stimulus (Fisher et al.). For example, if a child with autism was engaging in self-injurious behavior by banging his head on a table during difficult tasks, and the teacher removed the difficult task, the teacher might negatively reinforce the child’s self-injurious behavior.

Reinforcement, Differential

David McAdam¹ and Vicki Madaus Knapp²

¹Department of Pediatrics, University of Rochester Medical Center, Rochester, NY, USA

²Applied Behavior Analysis (ABA) Program, Daemen College, Amherst, NY, USA

Definition

Differential reinforcement is a behavioral analytic term related to the principle of reinforcement and the process of extinction. Differential reinforcement involves providing reinforcement contingent on the display of specific responses, not all responses. Differential reinforcement serves to refine or shape certain responses and reduces or eliminates other responses that do not meet the criteria for reinforcement. Responses that are differentially reinforced are intended to increase and meet a prespecified criterion defined in terms of some response dimension, including frequency, topography, intensity, duration, latency, or magnitude. The responses that do not meet the criteria for reinforcement are not reinforced, put on extinction, and decreased. Differential reinforcement is a useful and naturally occurring process

for increasing some behavior while eliminating other behavior. The effectiveness of differential reinforcement to increase or eliminate specific targeted behaviors has been demonstrated both in laboratory studies with nonhuman organisms (e.g., rats, nonhuman primates) and in applied studies conducted with children with autism and other developmental disabilities, thus illustrating the clinical usefulness and the generality of the procedure. In the applied literature, differential reinforcement of other behavior has been demonstrated to reduce socially maintained aggression, self-injury, and property destruction; differential reinforcement of alternative behavior has been demonstrated to increase such behaviors as alternative communication behaviors and engagement in functional activities.

Reinforcer

Mark Groskreutz

Special Education and Reading Department, The Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Synonyms

Reward

Definition

Reinforcement is demonstrated when a consequence is delivered following a behavior and subsequently that behavior is strengthened (e.g., occurs more in the future). When behavior increases (i.e., has been reinforced), the stimulus or event that followed the behavior (i.e., consequence) was a *reinforcer*. Thus, a reinforcer is any consequence for a response that has been shown to increase (or maintain) the future probability of that response. In other words, a consequence is only a reinforcer *if* the target behavior continues to occur or occurs more often. A common example could include praising a child for putting his/her toys away. A parent saying “way to go!” is a reinforcer if the child puts his/her toys away more in the future. If the child stops putting his/her toys away in the future, then praise, despite the parent’s best intentions, was *not* a reinforcer for the behavior of putting toys away. Research on operant behavior has consistently demonstrated the generality and importance of reinforcers in learning (i.e., increasing behavior; see Skinner 1938, 1953).

For a consequence to be a reinforcer, it must address some current motivation. For example, a high five will only increase a behavior (i.e., be a reinforcer) if the person currently wants a high five. On the other hand, if the person does not want a high five now, then the high five will not

reinforce current behavior (i.e., serve as a reinforcer). Similarly, a consequence will may be a reinforcer for some behaviors and not others. For example, a high five may be a reinforcer for the behavior of saying “thank you.” In contrast, a high five may not be a reinforcer for a different behavior, such as running 5 miles.

In working with individuals with autism spectrum disorders (ASDs), reinforcers will be needed to increase appropriate behaviors and, whenever possible, reinforcers should not be provided following inappropriate behaviors. Several assessment strategies are particularly important for identifying likely reinforcers for both appropriate and inappropriate behavior. Preference assessments can be used to identify likely reinforcers that may then be included in individualized interventions to increase appropriate behavior (e.g., DeLeon and Iwata 1996; Fisher et al. 1992). Alternatively, functional behavior assessments (FBAs) have been used to identify reinforcers for inappropriate behaviors (e.g., functional analysis; Iwata et al. 1994). Once reinforcers for inappropriate behaviors are identified, then interventions can be designed to increase an alternative, appropriate response and minimize or eliminate reinforcers for the inappropriate behavior (e.g., Carr and Durand 1985).

Reinforcers may be categorized as naturally occurring or contrived. In each case, the consequence is a reinforcer because it increased behavior. In the case of a naturally occurring reinforcer, the consequence is one that is commonly found in natural environments and situations. In contrast, a contrived reinforcer is a consequence that may not be common for that behavior in typical environments or situations. An example of a naturally occurring reinforcer is being called on after raising one’s hand in class. Alternatively, being given a token for raising one’s hand might be considered a contrived reinforcer. Naturally occurring consequences are generally preferable to contrived consequences because the behavior would be expected to continue in natural situations. However, for many individuals with ASDs, naturally occurring consequences may not reinforce their behavior. In other words, if the naturally occurring

consequence is the only consequence for their behavior, they will not continue to engage in that behavior. In these situations, contrived reinforcers will likely be needed before the learner will make progress. Over time, it may be possible to fade out (i.e., remove) the additional, contrived reinforcer (s), leaving only the naturally occurring consequences which may have become reinforcers.

Related Services

Michael Miklos

Pennsylvania Training and Technical Assistance Network, Harrisburg, PA, USA

Definition

Are supportive services provided by an educational agency such as a school district that are required to assist a child with a disability in obtaining benefit from special education. Related services are specified on a student's individual education plan. Included under the term are speech and language pathology and audiology services; interpreting services; psychological services; physical and occupational therapy; social work services; recreation, including therapeutic recreation; early identification and assessment of disabilities in children; counseling services, including rehabilitation counseling, orientation, and mobility services; and medical services for diagnostic or evaluation purposes. Related services also include school health services and school nurse services, social work services in schools, and parent counseling and training. The list of services provided here is not exhaustive; other services may need to be provided if an IEP deems that they are necessary for the student to obtain benefit from special education programming.

Relationship Between Autism Stigma and Informal Caregiver Mental Health

Chris Papadopoulos
University of Bedfordshire | Luton Campus,
Luton, UK

Definition

The relationship between autism stigma and informal caregiver mental health refers to the negative psychological consequences for informal caregivers when autism stigma is experienced. This has been evidenced to include depression, anxiety, psychological distress and well-being, psychological burden, and general mental health. “Autism stigma” refers to the negative social labeling and stereotyping ascribed by members of the general public toward autistic people (“public stigma” or “social stigma”) and/or their family and close associates (“courtesy stigma,” “associative stigma,” or “family stigma”). Autism stigma may also originate from health, social, educational, or legal professionals (“professional stigma” or “structural stigma”). “Self-stigma” (or “internalized stigma”) refers to autistic people accepting, agreeing, and incorporating negative stereotypes about autism into their own psychological identity. “Affiliate stigma” is a form of self-stigma. It occurs when informal caregivers of autistic people experience courtesy stigma and subsequently agree and incorporate the negative stereotypes directed toward them into their own psychological identity. The ways in which autism stigma is produced, manifested, and experienced are socially and culturally specific.

Relationship Development Intervention (RDI) Model

Evelynne Green
The University of Vermont, Burlington, VT, USA

Definition

The Relationship Development Intervention[®] (RDI) program is a comprehensive, parent-directed intervention designed to facilitate the social, emotional, and cognitive development of children, adolescents, and adults with autism spectrum disorders (ASD). The primary objective of the RDI program is to promote the development of dynamic intelligence through the restoration of a guided participation relationship (GPR) between the parent and individual with ASD. Gutstein (2009) suggests that dynamic intelligence is a set of mental processes, such as anticipating, evaluating, and integrating, which allow individuals to be flexible in their thinking, problem-solving, and coping with uncertain situations. It is the product of dynamic neural connectivity, which develops early on in childhood as a result of experiences provided by parents during guided participation

(Gutstein 2009). The concept of guided participation comes from the work of Vygotsky (1978) and Rogoff (1990). It is described as the process by which a more experienced adult scaffolds a child's competence and understanding by providing challenging experiences that are slightly above their current level of ability. Parents work in conjunction with a certified RDI consultant to establish a GPR through a parent-guiding curriculum and to facilitate the development of dynamic intelligence through a developmentally based dynamic intelligence curriculum (Gutstein 2009). Intervention objectives are targeted during daily activities, and the parent gradually assumes primary responsibility for implementation of the program with training from the RDI consultant.

Historical Background

The RDI program was developed by Dr. Steven Gutstein and Dr. Rachelle Sheely to “remediate information-processing deficits that are universal but by no means unique to persons on the autism spectrum” (Gutstein 2009, p. 23). The program came as a response to what Gutstein saw as a lack of intervention programs that addressed the core deficits of ASD and impacted the overall quality of life of individuals with ASD. The first book detailing the RDI program was published in 2000, followed by the publication of two RDI activity books, one aimed at young children (Gutstein and Sheely 2002a) and one aimed at children, adolescents, and adults (Gutstein and Sheely 2002b). In 2009, *The RDI Book: Forging New Pathways for Autism, Asperger's and PDD with the Relationship Development Intervention Program* was published and serves to replace previous works. The 2009 RDI book includes several modifications to the program including a systematized dynamic intelligence curriculum and a parent-guiding curriculum (Gutstein 2009). An RDI consultant training program, program for generalizing RDI in a school setting (Gutstein et al. 2007b), and an interactive Internet-based application have also been developed. The Internet-based

application, which was launched in 2007, is referred to as the RDI Learning System (RDILS). The RDILS allows parents, teachers, and RDI consultants in training to access information about the program, attend online seminars, and communicate with other individuals around the world. Additionally, parents may communicate with consultants through the RDILS, upload videos, and track their progress (Gutstein 2009). Gutstein (2009) indicates that currently, there are nearly 400 RDI consultants and consultants in training in 20 different countries.

Rationale or Underlying Theory

The RDI program was developed to remediate impairments in information processing that Gutstein (2009) suggests are the core deficits in individuals with ASD. Collectively, these information-processing impairments lead to challenges in “dynamic intelligence,” which allows individuals to be flexible thinkers, problem-solve effectively, collaborate with others, and cope with uncertain situations. This is contrasted with static intelligence, which is a representation of our knowledge, and includes abilities such as concept learning, categorizing, memorizing facts and procedures, and numerical computation (Gutstein 2009). Dynamic intelligence is the result of the elaborate neural integration that begins to develop in early childhood in response to exposure to cognitively challenging situations. Typically, the adult creates challenging learning opportunities through guided participation.

The concept of guided participation was first described by Rogoff (1991), who asserts that “both guidance and participation in culturally valued activities are essential to children's apprenticeship in thinking” (1991, p. 8). Guided participation occurs when the adult provides situations that are safe but slightly outside of the child's current independent capability, thus creating a cognitive challenge that requires problem-solving (Gutstein 2009). Participation in these uncertain situations facilitates the development

of complex and dynamic neural networks in the brain. Rogoff (1991) suggests that this relationship occurs naturally between caregivers and children and appears to be universal in some form across cultures.

According to Gutstein (2009), ASD is fundamentally a neurological disorder resulting from a paucity of dynamic neural interconnectivity in the brain. Recent research suggests that there is indeed evidence of neural underconnectivity in the brains of individuals with ASD (for a review, see Hughes 2007). Gutstein (2009) theorizes that a disruption of the guided participation relationship between parents and their children with ASD impedes the development of dynamic neural pathways while leaving static pathways generally intact. Thus, the RDI program was specifically designed to support the development of a guided participation relationship in order to facilitate dynamic intelligence development in individuals with ASD.

Goals and Objectives

As previously discussed, the fundamental goal of the RDI program is to facilitate the development of dynamic intelligence in individuals with ASD through guided participation. Dynamic intelligence is an overarching term used to refer to a set of skills, which typically develop in a sequential pattern. The RDI program employs a developmental approach to support the specific skills or objectives comprising dynamic intelligence. The dynamic intelligence curriculum utilized by the program currently consists of nearly 1,000 objectives that are targeted during intervention (Gutstein 2009). However, Gutstein (2009) indicates that the overarching goal of the RDI program is to enhance the quality of life of individuals with ASD. Thus, eight specific RDI goals, which represent characteristics determined to be essential to attaining quality of life, have been developed:

1. *Collaboration* – Refers to the ability to coordinate one's own thoughts and actions with a partner's to achieve a common goal.

Successful collaboration requires, among other things, negotiation, adaptation of communication, and monitoring of coordination.

2. *Deliberation* – Refers to the ability to approach unfamiliar situations and problems in a thoughtful and analytic manner. This may involve considering multiple approaches and perspectives before acting and anticipating the possible consequence of actions.
3. *Flexibility* – Refers to the ability to continually monitor and adjust actions based on past experiences, new information, and changing circumstances. It also involves the ability to manage problems that have no distinct right or wrong answer by considering multiple perspectives and thinking creatively.
4. *Fluency* – Refers to skills that are important to academic and employment success. This includes the ability to read for comprehension, summarize and synthesize information, write in an organized manner using appropriate syntax and spelling, communicate information through a variety of modes, and demonstrate competent use of computers, software, and other technical equipment.
5. *Friendship* – Refers to the ability to maintain relationships that are based on shared interests and experiences. Friendship requires empathy, loyalty, emotional coordination, and the ability to successfully manage conflict.
6. *Initiative* – Refers to the ability to independently initiate and complete tasks, set personal goals, and find alternate routes to success when things do not go as initially planned. It also involves the exploration of new ideas and skills even when they are challenging or unfamiliar.
7. *Responsibility* – Refers to the ability to act with integrity, take responsibility for one's own actions, honor commitments and promises, and care for items.
8. *Self-management* – Refers to, among other things, the ability to maintain healthy habits (e.g., hygiene, diet, sleep), effectively manage time, establish and maintain daily living routines that increase independence (e.g., paying bills on time), accurately evaluate personal strengths and limitations in relation to goals, and develop personal opinions, beliefs, and

values. Further, it involves the ability to effectively manage emotions and cope with negative emotions (e.g., stress, anger, frustration) in a productive manner.

Treatment Participants

The RDI program was designed specifically for individuals on the autism spectrum, including those with diagnoses of autism, Asperger's syndrome, and PDD-NOS. However, Gutstein (2009) indicates that consultants have reported success in working with individuals with other diagnoses such as reactive attachment disorder, attention deficit hyperactivity disorder, Tourette's syndrome, bipolar disorder, and seizure disorders. Because the program is highly individualized and flexible, treatment participants can vary greatly in terms of age and function. There are currently no set of age criteria. Participants may range in age from young children to adolescents and adults. Gutstein (2009) indicates that RDI consultants are trained to work closely with the family to individualize the program to be appropriate and effective for the participant. Additionally, the program is based on a developmental model, so no prerequisite skills are required to begin intervention. Instead, the intervention is tailored to fit the needs of participants with varying levels of social-emotional, language, and cognitive abilities.

Treatment Procedures

The RDI program is a parent-directed, developmentally based intervention, which aims to develop dynamic intelligence in individuals with ASD through guided participation. Parents are paired with an RDI-certified consultant in their area whose role is to customize the program based on the unique needs of the family and to facilitate parents in implementing the program. Consultants teach parents the tools that are essential to guided participation so that parents may become gradually more independent. Parents meet with consultants during live sessions to

practice assignments, discuss obstacles, and collaborate. Parents also communicate with consultants during the time between live sessions online through RDILS. There is no set time devoted to intervention each week. Instead, with the support of their consultant, parents learn how to effectively incorporate guided participation into daily activities so that this way of interacting with their child becomes an integral aspect of daily life.

There are four stages in the RDI program: Readiness (parent and child), Apprenticeship, Guiding, and Internalizing. The program utilizes the dynamic intelligence curriculum that was constructed over the past 10 years to represent the typical progression of skills and abilities contributing to dynamic intelligence (Gutstein 2009). The curriculum currently consists of nearly 1,000 developmentally sequenced objectives (Gutstein 2009). Each stage in the RDI program has a set of objectives, and each objective is further subdivided into lessons. Every lesson also has its own unique set of mastery criteria that the child must attain before moving to a more complex skill. The stages of the RDI program are briefly outlined below:

- *Readiness Stage* – During this stage, children are evaluated for obstacles to apprenticeship, which are addressed before full participation as an apprentice occurs. Potential obstacles include comorbid conditions such as seizure disorder, attention deficit disorder, anxiety, and sleep disorders and the failure to acquire prerequisite skills considered fundamental to successful involvement in a guided participation relationship (Gutstein 2009). At this stage, parents also learn to adjust their physical patterns of interaction and communication style and to identify, assess, and modify the expectations they hold for their child and for themselves.
- *Apprenticeship Stage* – A primary focus of this stage is the development of a trusting guide-apprentice relationship. Parents learn to carefully choose challenges that are appropriate for their child's unique needs and that are within their zone of proximal development while also developing an understanding that they cannot

necessarily predict how their child will react to the challenges they present. Parents also continue to adapt their communication style to support social reciprocity and mutual experience sharing.

- *Guiding Stage* – During this stage, children are introduced to the primary curriculum, which consists of several hundred objectives (Gutstein 2009). While previous stages focus primarily on scaffolding the child's active participation as an apprentice, the Guiding stage explicitly emphasizes the development of dynamic intelligence. Additionally, parents begin to assume greater responsibility in their role as a guide, as the fundamental skills for guided participation are transferred from the RDI consultant to the parent.
- *Internalizing Stage* – During this stage, parents assume primary responsibility for the tools of guided participation that they have learned from their consultant and learn to choose appropriate curriculum objectives for their child and create their own corresponding lessons. They also demonstrate greater independence, as time with their consultant is decreased. The curriculum objectives at this stage become increasingly complex, focusing primarily on internal processes, such as reflection and imagination, and older apprentices begin to take a more active role in the process of choosing objectives and creating lesson plans (Gutstein 2009). New communication partners and environments are introduced to facilitate the generalization of skills into real-world situations. For example, when the apprentice has mastered objectives with adults, a familiar peer may be introduced. Once competency with a peer has been demonstrated, the child may move on to a small group setting.

Efficacy Information

As of 2010, Gutstein and his colleagues have conducted two studies evaluating the efficacy of the RDI program. The initial study, which is outlined by Gutstein et al. (2007a), compared a group of children with ASD participating in the

RDI program for an average of 16 months and a group of children with ASD being treated with "more traditional intensive intervention methods" (p. 398). The authors report that more than 50% of children in the RDI group no longer met ADOS criteria for autism spectrum disorders and were more likely to participate in a typical classroom without support (Gutstein et al. 2007a). In comparison, the children participating in more traditional methods of intervention did not demonstrate significant improvements in core deficit areas, although they received greater direct therapist contact (Gutstein et al. 2007a).

In their follow-up study, Gutstein et al. (2007a) evaluated 16 children who participated in the RDI program between 2000 and 2005. Inclusion criteria for participants included a minimum of 30 months of participation in the RDI program between baseline and follow-up measures, an age of 20–96 months at the time treatment was initiated, a previous diagnosis of autism, Asperger's syndrome, or Pervasive Developmental Disorder-Not Otherwise Specified (PDD-NOS), and a baseline IQ score of at least 70 (Gutstein et al. 2007a). Effectiveness of the program was based on the following measures: scores on the Autism Diagnostic Interview-Revised (ADI-R; Rutter et al. 2003) and the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2002), a semi-structured flexibility interview, and educational placement.

Of the 12 participants for which baseline ADOS scores were available, 10 met diagnostic criteria for autism and 2 met criteria for autism spectrum. Following treatment, six participants met diagnostic criteria for autism spectrum, while ten were placed in the "non-autism" diagnostic category (Gutstein et al. 2007a). Similarly, mean scores for the sum of the communication and social interaction domains on the ADI-R were 10.6 at baseline and 2.4 at follow-up, indicating a significant decrease in impairment over the course of treatment (Gutstein et al. 2007a). On the flexibility interview, parent ratings indicating age-appropriate flexibility on the 10-item questionnaire increased from a mean of 16% at baseline to a mean of 71% at follow-up. Finally, in regard to educational placement, only two

participants were placed in a mainstream classroom without an aide at baseline. However, at follow-up, 10 out of 16 children were placed in a mainstream classroom without an aide.

As Gutstein and colleagues (2007) points out, there are several limitations that impact the generalizability of the reported findings. These include the lack of a control group, a small number of participants, a narrow range of age and IQ scores for the participants, and the geographical homogeneity of participants. Nonetheless, this study, along with the initial study previously discussed, provides preliminary evidence for the efficacy of the RDI program. However, these results should be interpreted with caution, as they are only preliminary and lack generalizability due to study limitations. Future research including larger samples and control groups will be fundamental in determining the potential benefits of the RDI program for individuals with ASD.

Outcome Measurement

RDI consultants track the participants' progress as they move through the stages of the dynamic intelligence curriculum. Every objective in the curriculum is subdivided into lessons, which each have a unique and observable set of mastery criteria. Consultants work closely with parents to determine if mastery criteria for a particular lesson have been achieved.

Qualifications of Treatment Providers

Individuals interested in applying for RDI certification are required to read *The RDI Book* (2009), hold a bachelor's degree, and complete an application for certification. RDI consultants may have a variety of professional backgrounds, including speech and language pathologists, psychologists, teachers, social workers, autism specialists, occupational therapists, and physicians (Gutstein 2009). Additionally, parents of children participating in the RDI program may also apply for certification with a recommendation letter from their RDI consultant. The certification process,

which typically takes 18 months to complete, includes four steps: (1) Beginning Seminar, (2) Intermediate Seminar, (3) Professional Supervision, and (4) Advanced Seminar. The Beginning and Intermediate Seminars focus primarily on the Family Guided Participation Program, while the Advanced Seminar focuses mainly on the Dynamic Education Program. During the professional supervision step, consultants in training (CIT) are required to work with two families under the supervision of an RDI-certified consultant.

Relationship Enhancement Methods

Barbara A. Cook

Department of Communication Disorders, Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Definition

Relationship enhancement methods are typically regarded as interventions that use strategies aligned to a developmental or social learning theoretical framework. Some interventions used to promote the development of social interactions and relationships are derived from the principles of applied behavior analysis (Cooper et al. 2007). Relationship enhancement methods focus on the development of appropriate emotional responses and relationship building for individuals, in natural contexts, under the guidance of peers or adults, and through repetition in small, manageable steps. These methods incorporate the manipulation of the individual's environment to increase social interaction, social engagement, and both sensory and emotional regulation (Quinn and Malone 2000). The overarching aim is to address the early and profound disruption in a child with Autism Spectrum Disorders interpersonal-affective relatedness (Hobson, 1990 as cited in Simpson 2005). Originally designed to improve the quality of interaction between the parent and child with ASD (Greenspan 1998 as cited in Marcus et al. 2005), many of these methods have been extended to improve the quality of interaction

between the individual with ASD and other key members of their immediate social circle, such as siblings, peers within the school environment, and members of their community (coaches, team members, club group members, etc.).

Historical Background

Relationship enhancement methods that occur within natural contexts find their earliest basis in the developmental theoretical frameworks suggested by Bandura (1977), Piaget (1950), and Vygotsky (1978). Collectively, these frameworks suggest that the development of social interaction occurs across a developmental continuum, in the context of naturally provided support and responding from significant others, within multiple environments. All provide a basis for activities that may be used for methods of intervention to support the social relationship interactions of individuals with ASD.

Bandura (1977), as a social-learning theorist, supported the understanding that interaction is determined by interdependence of the factors of behavioral actions, personal knowledge and understanding, and environmental scenarios, with varying degrees of influence of each factor depending upon the situation or context. Those who develop approaches based upon Bandura emphasize increasing self-regulatory capacities for interaction and observational learning of others within the environment. This theory may be the basis for activities that include modeling of behavior, such as peer modeling and video modeling (Hall 2018).

Piaget (1950) emphasized the link between cognition and affect. He believed that positive affect during interactive learning facilitated memory, increasing cognition. It is possible that collectively these would support the development of long-term social relationships. His framework includes creating opportunities for individuals to engage in sensorimotor activities as a precursor to language, an integral component to the development of social interaction.

Vygotsky (1978) promoted learning through a sociocultural context, suggesting that most

learning takes place in a social context. His work supports the use of peers and group structure to develop social relationships. Those who use Vygotsky's work as a foundation to their approach emphasize knowledge and use of a students' "zone of proximal development," which is his/her true potential, paired with scaffolding to increase social interaction skills. He supports the Piaget axiom that social interaction is fundamental for intellectual development (Hall 2018 p. 124).

Developmental patterns of socio-emotional development have been outlined by Daniel Stern (1985) and L. Alan Sroufe (1995). Stern (1985) shares the development of one's sense of self (awareness of emotions, self-regulation of emotions, perspective taking, joint attention linked to knowledge of others, interpersonal interaction) and its process in social relatedness. He presents four development stages of emotion (emergent self, sense of core self, subjective self, and verbal self) that begin preverbally and later emerge through language or self-reflection. Approaches based upon Stern's work provide opportunities to increase this sense of self through activities such as those that encourage joint attention and imaginative play (Hall 2018, p. 125). Sroufe (1995) supports the understanding that emotion follows a developmental pattern, strongly linked to social development, known as socio-emotional development. He outlines the emergence of emotional development over the first 54 months of life (Hall 2018, p. 126) and notes the shift that occurs within the developmental process as one that moves from dyadic regulation (supported by another) toward self-regulation in the individual. Approaches based upon Stern emphasize both social and emotional development simultaneously and use of the support of adults and peers during a variety of fantasy and imaginary play activities (Hall 2018, p.126).

Rationale or Underlying Theory of Example Programs

Relationship enhancement methods are mostly grounded in the theoretical frameworks related to social learning theory, cognitive development,

and socio-emotional development. Some include techniques developed through applied behavior analysis as a means of encouraging the development of skills required for social interaction. Current published intervention programs exist that promote relationship enhancement and align to these theoretical frameworks. A few are included below; it is noted that all provide a manual or guide to direct means of implementation. The following provides a brief overview of each.

The Developmental Individual-Difference, Relationship-Based model (DIR)/Floortime Approach™, developed by Stanley Greenspan, M.D., reflects Piaget's and Sroufe's frameworks, respectively, with emphasis on sensori-motor activities and linking emotion to the growth of the mind and brain. (Hall 2018, p. 144). The primary focus is relationship-based, with primary caregivers and/or practitioners assisting the individual as they move through the phases of emotional development, capitalizing on these stages of emotion using activities of interest and motivation to the individual.

Relationship Development Intervention, developed by Steven Gutstein and Rachelle Sheely, also reflects Sroufe's framework, with emphasis on social-emotional development through guided participation with the caregiver (Hall 2018, p. 147). The caregiver follows a scope and sequence of socio-emotional development and implements activities designed to model and scaffold the identified set of skills outlined by the authors.

The Denver Model, developed by Sally Rogers, Ph.D. and Diane Osaki, OTR, reflects Stern's framework, with an emphasis on utilizing play for all therapies and activities to enhance social interaction, in a pleasurable manner (Hall 2018, p. 132). At the core of this program is a strong emphasis on social relatedness and social interaction, including parents as key to implementation. Additionally, this program incorporates techniques based on the principles of applied behavior analysis in an effort to further encourage the development of social interaction.

The Social Communication, Emotional Regulation, Transactional Supports (SCERTS) model, developed by Barry Prizant, Ph.D., Amy

Wetherby, Ph.D., Emily Rubin, M.S., Amy Laurent, Ed.M., OTR/L, and Patrick Rydell, Ed. D., reflects developmental theory, learning theory, and family systems theory. The emphasis placed upon emotional regulation relates to the work of Sroufe, with the connection of emotion on mind and brain development (Hall 2018, p. 126). There is a strong emphasis on the inclusion of a multi-disciplinary team to support the development of social interaction and relationships across multiple environments.

The Program for the Evaluation and Enrichment of Relational Skills (PEERS), initially developed by Elizabeth Laugeson and Fred Frankel (2010), reflects developmental theory related to how individuals form and maintain friendships. The emphasis is placed upon development of conversational management as well as key factors that influence relationship enhancement with peers.

Goals and Objectives

The goals and objectives written for these methods of intervention will address social interaction and emotional development, with emphasis upon natural contexts, including specific people within specific environments. A published program may include a specific scope and sequence meant to be followed; however, each emphasizes individuality and the necessity to establish goals and objectives relevant to the individual client. Potential goal areas will be based upon missed developmental or functional milestones and will likely highlight development of joint attention, intimacy, reciprocal communication, expression of emotions/feelings, problem solving, conversational management, and increased flexibility. There typically is an emphasis upon functional communication within natural settings, opposed to rote learning of specific, unrelated language concepts. Emotional regulation and availability of the individual to socially interact are paramount. Therefore, goals to increase the individual's ability to state current levels of regulatory behavior and that promote the ability to engage

in self-advocacy will be needed. Additional goals and objectives should focus upon strengthening social communication and social interaction through play and friendship development (Laugeson et al. 2014; Laugeson and Frankel 2010; Prizant et al. 2006; Gutstein 2000; Rogers et al. 2001).

Treatment Participants

Most individuals receiving programming based upon relationship enhancement methods are age 8 or younger. However, more recently, these approaches are being implemented with adolescents and adults (i.e., Laugeson et al. 2014). The authors of the programs indicated have developed activities for individuals of all ages with severe to mild Autism Spectrum Disorders, Asperger's Syndrome, and other developmental disabilities with varying cognitive ability levels. Family members and peers are integrated as key participants to insure success in generalization (Laugeson and Frankel 2010; Prizant et al. 2006; Rogers et al. 2001; Gutstein 2000; & Koegel and Koegel 1995).

Treatment Procedures

Generally, relationship enhancement methods follow the developmental level of the individual, utilizing activities in one to one and small group settings to increase social reciprocity for the purpose of developing appropriate social interactions, across all people, and all settings. The procedures and activities are driven by the particular program being implemented and based upon the strengths and weaknesses of each individual. The general, primary mode of delivery is through play based or natural contexts, with emphasis upon symbolic and pretend play. The practitioner follows the lead of the child or adult, guiding reciprocal turn-taking, responding to the individuals' initiations, matching the individuals' communication level, and modeling expected socially relevant responses. Scaffolding and embedded learning are key strategies, utilizing visual

supports, particularly for those individuals who have not yet developed adequate language or speech. Key implementers include Special Educators, Speech/Language Pathologists, School Psychologists, Clinical Psychologists, Occupational Therapists, other related disciplines, caregivers, siblings, and same age peers. The reader is referred to each specific method for more in-depth information regarding their various treatment procedures (Laugeson et al. 2014; Laugeson and Frankel 2010; Prizant et al. 2006; Rogers et al. 2001; Gutstein 2000; Koegel and Koegel 1995).

Efficacy Information

Given the complex nature of relationship enhancement methods, it is not surprising that one does not find empirical evidence for this broad category. Instead, it will be necessary for practitioners to conduct a review of literature regarding each published program. Additionally, it will be possible to conduct an analysis of each published program to identify discrete intervention strategies embedded within the programs then determine whether there is empirical evidence to support the discrete procedures that are part of the larger intervention model. Given the limited space for this article and the dearth of information available, the reader is directed to review the work conducted by the National Professional Development Center on Autism, The National Clearinghouse on Autism Evidence & Practice, and the National Standards Project for reviewed articles and currently regarded evidence-based practices for comparison. Additionally, the reader may locate detailed accounts of the listed programs found in this article within the Encyclopedia on Autism, the publisher of this article.

Outcome Measurement

Each method provides guidelines for outcome measurement. Many include case study notes, video diaries, individual progress notes, and completion of specific curricular goals and objectives.

Some include additional supplemental evaluations conducted by the Speech/Language Pathologist, the Occupational Therapist, and/or Clinical or School Psychologist working directly with the individual (Laugeson et al. 2014; Prizant et al. 2006; Rogers et al. 2001; Gutstein 2000; Koegel and Koegel 1995).

Qualifications of Treatment Providers

Each individual relationship enhancement method has its own list of qualifications for treatment providers. Generally, most of these methods support parents, family members, peers, and therapists as possible providers and provide a variety of workshops and trainings to assist treatment providers in implementing their approach. A few of the methods do require additional training to receive certification from their agency, indicating required knowledge and skill to implement the activities and strategies associated with the methodology (Laugeson et al. 2014; Prizant et al. 2006; Rogers et al. 2001; Gutstein 2000; Koegel and Koegel 1995).

Definition

Relaxation techniques consist of a variety of strategies that are integrated into behavioral therapies, with the common feature of decreasing physical tension within the affected individual, typically associated with their anxiety or other negative affective experiences (e.g., pain, traumatic memory).

Historical Background

Relaxation techniques have been used for centuries in Asia by physicians and healers in order to aid in the treatment of an assortment of health problems from infants to the elderly. The

technique, although used in western medicine, has not played as a central role in the treatment of major health problems and has generally been used as part of a larger treatment package or considered a type of complementary and alternative medicine (CAM). Relaxation training has been used in the treatment of physical, psychological, and emotional problems, and the methods range from different forms of massage and chiropractic treatments to the use of visualization techniques and virtual reality hypnosis. The most common form of relaxation therapy currently used is progressive muscle relaxation (PMR; Jacobson 1970), which involves alternately tensing and relaxing various muscle groups around the body. PMR originated from the theory that a psychobiological state, neuromuscular hypertension, is the basis for a variety of negative emotional states and psychosomatic diseases (Jacobson 1938). For individuals with autism, preliminary clinical trials have found massage therapy to be associated with decreased autism-specific behaviors such as stereotypies and aversion to certain stimuli as well as increasing on-task behavior and social relatedness in school and decreasing sleep problems at home (Escalona et al. 2001; Field et al. 1997).

Rationale or Underlying Theory

The modern rationale for relaxation therapy is directly related to the notion that people respond to situations perceived to be threatening in three specific modalities – physiologically, behaviorally, and subjectively (or cognitively) – each feeding on the other resulting in a cycle of increased negative reactions. In addition, an important element of psychological distress is an elicitation of a general stress response involving the sympathetic nervous system which is responsible for up- and downregulating numerous homeostatic systems. The resulting activation manifests by enervating the muscular, cardiovascular, and behavioral subsystems to name a few. Relaxation therapy aims to reverse the generalized stress response by deactivating arousal of one of its components, the muscular subsystem. By deactivating this

single subsystem, the patient may be able to reduce activation in other subsystems (Gellhorn and Kiely 1972). In addition, Jacobson (1938) asserted that the relaxation of muscles would lead to relaxation of the mind “because an emotional state fails to exist in the presence of complete relaxation of the peripheral parts involved” (Jacobson 1938, p. 218), an application of the James-Lange theory of emotion (Lang 1994). Therefore, relaxation therapy aims to inhibit the generation of anxious thoughts and emotions and undo the effects of muscular tension on related somatic processes.

Goals and Objectives

Relaxation therapy has been used to treat a variety of disorders ranging from hypertension to stress, insomnia, and headaches. The most prevalent use of these relaxation techniques, in particular muscle relaxation techniques, has been in the treatment of anxiety. The basic therapeutic notion of relaxation therapies is that people experiencing tension, stress, and anxiety can find relief from emotional distress and its physiological accompaniments by learning to reduce muscle tension (Conrad and Roth 2007).

Treatment Participants

Relaxation therapies have been shown to be beneficial to a wide range of individuals (from infants to the elderly) with varying treatment needs such as migraines, behavior problems, sleep problems, and autism-related behaviors, although the level of evidence varies widely across applications (Azrin et al. 1975; Escalona et al. 2001; Reese et al. 1998; Thompson et al. 2010). For example, there is a substantial evidence base for relaxation therapy in the treatment of chronic headache. Headaches are understood to be the result of a complex interaction between biology, environment, behavior, cognition, and emotions (Buse and Andrasik 2009). A muscular component plays a central role in the presence and severity of such headaches, thus providing the rationale for

relaxation therapy. While pharmacological treatments for headaches (and pain in general) are frontline treatment options, some individuals do not wish for, or respond well to, medication. In these cases, relaxation therapy has proved to be a viable alternative (Kroner-Herwig et al. 1998). Anxiety disorders are the most common conditions to be successfully treated with relaxation techniques, particularly muscle relaxation therapies. While there are a limited number of empirical studies that support the efficacy of relaxation therapy when compared with other evidence-based treatments, a number of well-designed randomized controlled trials have been conducted (Ost and Breitholtz 2000; Richter 1984). Relaxation techniques have also been tested for the treatment of specific behaviors in youth with autism spectrum disorders (ASD) (see section “[Efficacy Information](#)” below).

Treatment Procedures

Relaxation techniques typically take place in a clinic-based setting with a mental health professional on an individual basis. Treatment usually begins with an introduction of the rationale to the patient as well as several sessions of “training” on the relaxation process. While the first several sessions are heavily therapist-driven, as treatment progresses, the patient starts to take over the process of implementing the relaxation techniques with practice outside of the therapy room serving as a key component for generalization across settings (Mullins and Christian 2001; Ost 1987; Richter 1984). However, several studies have found that successful implementation of relaxation techniques by paraprofessionals and non-experienced parents can be achieved (Gasalberti 2006; Russell and Wise 1976). Treatment providers are typically seen as coaches in that the goal is to teach the individual strategies in order for patients to eventually recognize when to use relaxation techniques and effectively implement them when needed. Treatment is usually provided during several weeks of sessions with a combination of practicing in session and at home (Ost 1987). The specific number of treatment sessions

associated with successful remittance of problems is undetermined at this time, as studies have ranged from as few as one session a day for two weeks to as long as one time a week for 15 weeks. Relaxation therapies, regardless of which method is used, all focus on the systematic management and reduction of physical tension.

Given the long-standing history of progressive muscle relaxation training to address anxiety in youth, a general outline of the methods is provided (Jacobson 1938; Kendall 1994; Ost 1987). The basic procedures involve the client sitting in a comfortable chair as the therapist instructs them in alternating contracting and releasing of different muscle groups, typically beginning with the large muscle groups (e.g., arms and legs) and progressively moving to the smaller groups (e.g., face and hands). The client learns to recognize the contraction and relaxation in a certain order, simultaneously relaxing all parts that have been previously relaxed. After mastering the relaxation sequence, clients are taught to relax their muscles in real-life situations.

It should be noted that relaxation techniques are often provided as a component of a larger cognitive behavioral therapy treatment program (e.g., Kendall 1994; Wood and McLeod 2008).

Efficacy Information

Some difficulties arise when evaluating the efficacy of relaxation therapies due to the wide range of dependent variables used as well as the imprecise definition of relaxation strategies used in studies. Due to the variety of disorders that are targeted with relaxation therapy, measures vary greatly from study to study. Studies focusing on relaxation to decrease anxiety use measures of anxiety symptoms for their outcome measures, while studies using relaxation to decrease disruptive behavior problems may measure the total number of outbursts over a specific amount of time. In addition, several measures are used to capture the multiple features of a single disorder within a study, thus making it difficult to compare treatment efficacy across studies. However, findings from studies have shown that some relaxation

therapies may be as effective as other behavioral treatments for certain symptoms when they are accompanied by other supportive measures and maintained for an extended period of time (Ost and Breitholtz 2000; Richter 1984). Ost and Breitholtz (2000), in a randomized controlled experiment, compared cognitive therapy and an applied relaxation therapy in the treatment of adults with generalized anxiety disorder. At post-treatment, they found that patients from both groups improved on all independent assessor ratings and on eight of the nine self-report measures with no differences observed in either condition. In addition, a comparable number of participants in each group showed significant clinical improvement. On average, participants were able to maintain these improvements for an average of 13.7 months. Long-term follow-up studies have shown that gains made during treatment are typically maintained for an extended period of time. Other studies also have found that treatment outcomes were maintained for several months after treatment completion with one study of finding that positive results from relaxation therapy were maintained at a follow-up of 19 months (Ost 1987; Reese et al. 1998; Sherman et al. 2010). It should be noted that more evidence has accrued favorable to relaxation therapy for adults with psychological difficulties than with children.

Escalona and colleagues (Escalona et al. 2001) found that children with ASD who received massage therapy, when compared with a control group, exhibited fewer stereotypic behaviors and more on-task and social relatedness behaviors as well as fewer sleep problems posttreatment. Treatments with relaxation components focusing on the reduction of self-injurious and disruptive behaviors have been found to be successful in individuals with ASD as well (Mullins and Christian 2001; Reese et al. 1998). Mullins and Christian examined the effect of a progressive relaxation training program on disruptive behavior problems of a 12-year-old boy with autism. Training consisted of presenting the boy with the steps of the relaxation process along with a training book that provided visual cues while the researchers gave minimal verbal prompts throughout the process. Results from their study indicated that a

decrease in the duration of disruptive behaviors occurred when relaxation training preceded a leisure activity session (compared with no relaxation prior to activity). In addition, the percent of overt relaxed behaviors increased following training and results were acquired through minimal assistance after training. Reese et al. examined the effects of a multifaceted intervention program to reduce disruptive behaviors of individuals with autism and mental retardation living in a community group home. One component of the treatment was a relaxation breathing exercise taught to the participants as well as teaching them how to request a break to relax when exhibiting pre-disruptive behaviors. While the results are somewhat mixed as to the efficacy of the relaxation component, they did find that the participants could relax when prompted (although counselors could not always anticipate when they needed to be prompted) and were able to increase the number of times they requested a break to relax.

Reasons as to why and how relaxation therapy works have been difficult to come by (Conrad and Roth 2007), and research into identifying key elements of the techniques has been urged by researchers in this field (Sherman et al. 2010).

Outcome Measurement

Outcome measures vary with regard to the targeted behavior of the treatment. When treating individuals with anxiety, anxiety measures are typically used pre- and posttreatment in order to determine if the level of anxious symptoms decreased following treatment. Measures may be completed through diagnostic interviews with the patient such as the Anxiety Disorder Interview Schedule: Parent and Child Versions (ADIS; Silverman and Albano 1996) or through self-report measures such as the State-Trait Anxiety Inventory (STAI; Spielberger et al. 1970). During neurofeedback training, individuals are made aware of their brain activity through the use of electroencephalograph (EEG) with the goal being to control central nervous system activity (Hughes and Davis 1980; Thompson et al. 2010). One drawback to the use of relaxation techniques is

the lack of measurement of actual relaxation behaviors, making it difficult to determine if a relaxed state was achieved. In more recent studies, some researchers have attempted to address this limitation by using such measures as the Behavioral Relaxation Scale (Poppen 1988), an indicator of relaxation shown to have a positive correlation between those scores as well as electromyography recordings and self-report measures. Overall, there are a limited number of tools or instruments that are used to measure the level of relaxation obtained by the individual. Measures are typically focused on the behaviors that are the target of the relaxation therapy, which can vary widely due to the use of these techniques on an assortment of conditions.

Qualifications of Treatment Providers

Depending on the type of relaxation therapy used, the qualifications of the treatment providers differ. Most relaxation therapies are conducted by a licensed therapist who is able to help the individual recognize the distressing or uncomfortable feelings that need to be targeted as well as guiding the individual through relaxation techniques. For massage-based relaxation therapies, a licensed massage therapist, physical therapist, and even parents have been trained to use massage to reduce pain and promote relaxation (Gasalberti 2006). However, there have been some relaxation therapies that have been found to reduce problem behaviors, such as anxiety, through means that have yet to be understood and do not require a licensed therapist to provide the treatment (e.g., standard scripts, audiotaped instructions; see Kendall 1994). Researchers are beginning to investigate the mechanisms behind these therapies to understand efficacy and how to best implement them (Conrad and Roth 2007; Sherman et al. 2010).

Repertory Grid Process for Person-Centered Assessment of Social Cognition for Adolescents with Autism Spectrum Disorder

Sean Hess¹, Trisha Self² and Anthony DiLollo²

¹Rehabilitation Services, Wesley Woodlawn Hospital & ER, Wichita, KS, USA

²Wichita State University, Department of Communication Sciences and Disorders, Wichita, Kansas, USA

Definition

A person-centered process for assessment and exploration of the social cognitive personal construct systems of adolescents with ASD with average or above-average intelligence and language skills. The process is modified from the typical flexible format presented in the repertory grid literature (see Fransella 2003; Fransella et al. 2004; Kelly 1955) to provide visual structure and a unique prompting hierarchy to help adolescents with ASD engage in the process.

Remembering to Remember

- [Prospective Memory in Autism Spectrum Disorder](#)

Remembrance

- [Memory](#)

Remeron

- [Mirtazapine](#)

Historical Background

Social pragmatic communication deficits are core to autism spectrum disorder (ASD; American Psychological Association 2013). Social skills groups designed to help adolescents with ASD learn and/or improve their ability to communicate with others in social environments are commonplace; however, the process of evaluating adolescents with ASD to determine their baseline social pragmatic communication skills, inform goals for therapy, and provide therapeutic interventions varies. Many standardized (and a few non-standardized) methods of evaluating social skills of such individuals typically entail gathering observational data of social behaviors an adolescent displays and those behaviors he or she does not display, then ranking those

social skills on Likert-type rating scales (Bellini 2006; Bowers et al. 2007, 2010; Carrow-Woolfolk 1999; Constantino and Gruber 2012; Garcia-Winner 2011; Gilliam and Miller 2006; Gresham and Elliott 2008; Kleiman 2003; Phelps-Terasaki and Phelps-Gunn 2007). Although such approaches can identify social skills demonstrated by the individual, they are limited to a “snapshot” of observable behaviors that arise as a function of the immediate environment and fail to access underlying cognitions and attitudes related to social interactions. Literature from personal construct psychology suggests that these underlying cognitions and attitudes are part of an organized system of personal constructs that can be accessed through a process called the repertory grid assessment (Fransella 2003; Fransella et al. 2004; Kelly 1955). Although repertory grids have been used by clinicians and researchers for many decades, they have only recently been used with individuals with ASD (Hare et al. 1999; Hess et al. 2018).

Current Knowledge

Hare et al. (1999) used repertory grids to explore the social root systems of adults with Asperger’s syndrome living in a group home. The residents demonstrated significant difficulties in their lives, including poor social interfacing with caretakers and with each other and some reportedly demonstrated suicidal ideation. After other attempts to evaluate and improve the social interaction skills and lives of the residents failed, a modified repertory grid process was attempted. Researchers found that, by engaging participants in the repertory grid process with some modifications to scaffold deficits in executive functioning seen in Asperger’s syndrome, the residents were able to engage in the repertory grid process and establish repertory grids. Data from the repertory grids provided researchers and caretakers with first-person insight into the residents’ social cognitive processes that could be used to enhance caretakers’ efficacy of caring for residents.

Hess et al. (2018) explored the potential utility of repertory grids with adolescents with ASD. In a study with five adolescents with ASD with average or above-average language and intelligence skills, Hess, Self, and DiLollo found that by providing visual structure and verbal prompting, these adolescents were able to successfully engage in the repertory grid process. Further, the modified repertory grid process provided a venue for participants to describe, via semi-structured conversational discourse within the structured framework of the process, social interactions with people over the course of their lives that shaped how they conceptualized others in social environments. The grid data delineated how each individual differentiated friend-from-foe and even how they thought of themselves and their hypothetical ideal selves and what behaviors/aspects of their current social selves they would change to become their ideal social selves. Beyond providing researchers with descriptions of the individuals’ social cognitive personal construct systems, the process also provided insight of surprising depth of each individual’s social cognitive awareness that helped researchers better understand why certain social behaviors were or were not observed, further distinguishing the repertory grid assessment from the standard approach.

Future Directions

The use of repertory grids with adolescents with ASD with average or above-average intelligence continues to be explored. Further research is needed to determine the utility of repertory grids in a variety of settings (e.g., public schools, group homes, family homes). It will be essential to determine how clinicians can best use the data collected during the repertory grid process to design effective therapeutic interventions for individuals who are receiving therapy services and to potentially advocate for treatment for those adolescents with ASD who are not receiving services.

Repetitive Behavior

Johannes Rojahn¹ and Lisa J. Meier²

¹Department of Psychology, George Mason University, Fairfax, VA, USA

²Department of Psychology, George Mason University, Falls Church, VA, USA

Definition

The term “repetitive behaviors” refers to abnormal behaviors that are characterized by repetition, rigidity, inappropriateness, and lack of adaptability (Bodfish 2007). They include motor stereotyped behaviors, self-stimulatory behaviors, self-injurious behaviors, compulsive or sameness behaviors, and verbal repetitive behaviors such as echolalia (Bodfish et al. 2000). Repetitive behaviors may become problematic when they occupy a significant portion of the individual’s waking hours, interfere with participation in other life activities, interfere with appropriate social interactions, disrupt the learning of more appropriate behaviors, or in the case of self-injurious behavior cause significant bodily damage. The specific function of repetitive behaviors in autism is unknown, but hypothesized functions include stress reduction, reward/gratification, and sensory stimulation (Mason 1991). Individuals with autism who engage in repetitive and restricted behaviors often experience anxiety, acute distress, or agitation if the behaviors are interrupted (Lam and Aman 2007).

Restricted and repetitive behaviors and interests are not exclusive to autism spectrum disorders and are often found in individuals with other developmental disorders such as mental retardation/intellectual disability or developmental delays, certain psychiatric disorders including schizophrenia and obsessive-compulsive disorder, several genetic syndromes, and medical conditions such as Parkinson’s disease and Tourette’s disorder (Bodfish et al. 2000; Moss et al. 2009; Richler et al. 2007) and in individuals with sensory disorders such as the visually impaired (Tröster et al. 1991). Repetitive behaviors are

frequently reported by mothers of typically developing children as well, particularly in early childhood (Leekam et al. 2007). However, there appear to be qualitative and quantitative differences between repetitive behaviors of children with autism and those who develop typically (Arnott et al. 2010; Richler et al. 2007), in the developmental pattern of such behaviors over time (Richler et al. 2010) and in the prevalence of repetitive behaviors even compared to children with intellectual disability (Bodfish et al. 1995).

The presence of restricted, repetitive, and stereotyped patterns of behavior, interests, and activities is one of the three core symptom clusters used to diagnosis autistic disorder according to the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revisions (American Psychiatric Association 2000). Within this domain, the DSM-IV-TR defines repetitive behaviors specifically as “(a) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus; (b) apparently inflexible adherence to specific, non-functional routines or rituals; (c) stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements; (d) persistent preoccupation with parts of objects” (p. 75). The proposed DSM-V (American Psychiatric Association 2010) includes restricted or fixated behavior, interests, and activities as a required symptom for a diagnosis of autism spectrum disorder.

The DSM-IV-TR includes the diagnosis of stereotypic movement disorder that is defined as “repetitive, seemingly driven, and non-functional motor behavior (e.g., hand shaking or waving, body rocking, head banging, mouthing of objects, self-biting, hitting own body (p. 134).” The diagnosis includes a specifier of “with self-injurious behavior” if the repetitive behavior results in bodily damage that requires specific treatment or would require treatment if protective measures were not used. The diagnosis of stereotypic movement disorder also requires that the repetitive behavior is not a symptom of a pervasive developmental disorder such as autistic disorder, not a behavioral tic, not a compulsive behavior that is part of an

obsessive-compulsive disorder, and not trichotillomania or hair pulling that is considered an impulse-control disorder not elsewhere classified. The need to exclude or rule out other diagnoses that could better account for the observed repetitive or stereotyped behaviors illustrates the lack of specificity of repetitive behaviors to any one disorder.

The ICD-10 (International Classification of Diseases-Tenth Revision) is the current version of the international standard diagnostic classification for all general epidemiological purposes, for health management purposes, and for diagnostic clinical use. Childhood autism is included in the ICD-10 and is diagnosed on the basis of similar symptom clusters to the DSM-IV, one of which is the presence of restricted, stereotyped, and repetitive behavior (World Health Organization 2007). The ICD-10 also includes a diagnostic category called stereotyped movement disorders. These disorders are characterized by voluntary, repetitive, stereotyped, and nonfunctional movements (often rhythmic) that are not part of a diagnosed psychiatric or neurologic condition. Similar to the DSM-IV-TR, stereotyped movement disorders can be self-injurious or non-self-injurious.

A review of the research on the phenomenology of repetitive behaviors in autism provided useful operationalized definitions of subtypes of repetitive behavior (Lewis and Bodfish 1998). The authors were careful to try to distinguish among the different subtypes toward the goal of better defining and thus more accurately assessing for the presence of repetitive behaviors in autism (see Table 1). Restricted behavior and ritualistic behavior were later added as specific conceptual subtypes, and Akathisia and dyskinesia have since been removed as subtypes.

A five-conceptual groupings model of restricted repetitive behaviors proposed by Bodfish and colleagues that are assessed with the *Repetitive Behavior Scale-Revised* (RBS-R) (Bodfish et al. 2000) has received empirical support (Lam and Aman 2007; Bodfish et al. 2000).

The five factors that emerged in factor analysis are (1) *rituals/sameness*, (2) *self-injurious behavior*, (3) *stereotypic behavior*, (4) *compulsive behavior*, and (5) *restricted interests* (Lam and Aman 2007). The RBS-R has six subscales

Repetitive Behavior, Table 1 Subtypes of repetitive behaviors

Classification	Definition
Akathisia	Movement disorder that can manifest as repetitive and restless movements such as pacing or a hyperkinetic restless state such as the inability to remain still when sitting or standing
Compulsions	Repetitive intentional behaviors that appear to follow certain rules
Dyskinesia	Repetitive and involuntary movements that can be subdivided into three types: nonrhythmic and jerky movements (chorea) or slow, writhing movements (athetosis), or slow and sustaining muscle tensing (dystonia)
Echolalia	Repetitive use of speech immediately, such as repeating all or part of what was just heard or after a delay. Echolalia can be “parrot speech” defined as repeating whatever is heard and “perseverative speech” in which a small number of words or phrases is repeated in a ritualistic or persistent manner
Obsessions	Repetitive, persistent thoughts, impulses, or images that are experienced as intrusive or inappropriate and that caused marked anxiety or distress in the individual
Perseveration	Behavioral responses in which nonaberrant adaptive responses are repeated beyond what is necessary to reach a goal. This can include the perseveration of attention
Restricted behavior	Behavior with a limited range of focus, interest, or activity
Ritualistic behavior	Performing activities of daily living in a similar manner
Sameness	Involves overall repetitive routines and preferences rather than the discrete repeated acts or thoughts that define compulsions or obsessions
Self-injury	Repetitive motor movements that result in bodily injury or have the potential to result in bodily injury to the individual engaging in the behavior
Stereotypy	Repetitive and seemingly purposeless body movements, movements of body parts, or use of the body to generate movement in objects
Tics	Often considered involuntary movements, tics are repetitive behaviors that can be simple or complex and that are executed repeatedly in an “explosive” manner and out of context

because it assesses ritualistic behavior and sameness behavior separately although they load as a common factor.

Repetitive behaviors have also been subdivided into two conceptual categories referred to as “lower order” and “higher order” (Bodfish 2007). Lower order repetitive behaviors are repetitive motor movements such as repetitive manipulation of an object, body rocking, and hand flapping or a repetitive self-injurious behavior such as head banging. Higher order repetitive behaviors are more complex and are cognitive behaviors such as circumscribed/restricted interests, insistence on sameness, or compulsions.

An alternative two-factor categorization of repetitive behaviors has also been proposed for young children and has received research support (Richler et al. 2007). The two factors are described as a *repetitive sensory motor* factor (RSM) and an *insistence on sameness* factor (IS). The RSM factor includes behaviors such as hand/finger movements, complex body mannerisms, repetitive use of objects, and unusual sensory interests. The IS factor includes behaviors such as rituals and compulsions and resistance to or distress with change. It is suggested that RSM behaviors are more common in very young children than IS behaviors.

Historical Background

Repetitive behaviors as a core feature of autism were recognized as early as 1943 when Dr. Leo Kanner first described case studies of 11 children that he conceptualized as having an “autistic disturbance of affective contact” (Kanner 1943). These children had a “dread of change and incompleteness” (p. 246) that led to monotonous and repetitive behaviors and limitations in the range of spontaneous activity. Rituals had to be carried out from beginning to end without variation. Kanner also described the anxiety and distress that the children seemed to experience whenever the sameness of a chain of behaviors, including verbal behaviors, was broken. Kanner hypothesized that these repetitive behaviors and the insistence on

sameness were a part of the child's "good relation to objects" (p. 246) as opposed to their lack of interest in and poor relations to people.

In 1944, Dr. Hans Asperger, for whom Asperger's disorder is named, described four boys ages 6–11 years who had good language and cognitive skills, yet marked impairment in social interaction as having "autistic psychopathy" (Klin et al. 2000) or more accurately translated as "autistic personality disorder" (Volkmar and Klin 2000). Asperger also described that these four and a larger sample of children also had pre-occupations and unusual circumscribed interests that were the focus of much of their life and that interfered with the acquisition of necessary skills (Volkmar and Klin 2000). Asperger also noted that similar traits were often seen in other family members, particularly fathers.

Current Knowledge

Epidemiology of Repetitive Behaviors

Because the presence of restricted or circumscribed interests or repetitive or stereotyped behaviors is part of the diagnostic criteria for autism, it is understood that the prevalence of repetitive behaviors of some kind is 100% in this population which is generally supported by research (Bodfish et al. 2000; Campbell et al. 1990; Shay et al. 1993).

Research suggests the possibility of age-related differences in the patterns of particular restrictive repetitive behaviors (RRBs) in individuals with autism spectrum disorders, a possible relationship between level of intellectual functioning and patterns of RRBs, and possible interactions between age and level of functioning. However, research findings are inconsistent and seem to depend upon the age range of the sample, the specific subtypes of repetitive behaviors, and the instrument used to measure the behaviors.

Age. In general, RRBs seem to be less severe and less frequent in older compared to younger children with autism. Similarly, adults with autism display fewer repetitive behaviors than children, suggesting that RRBs may decrease over the

lifespan (Esbensen et al. 2009). Younger children with ASD may be more likely to exhibit motor and sensory repetitive behaviors, whereas older children may be more likely to exhibit more complex repetitive behaviors (Militeri et al. 2002). Among specific subclasses of RRBs, stereotyped movements and restricted range of interests appear to be less frequent among older individuals, whereas rituals/sameness appears to be more frequent in this group. Self-injurious behaviors and compulsive behavior subtypes do not show differences across age groups (Lam and Aman 2007).

Level of functioning. Research findings have also suggested that the expression of RRBs may be influenced by level of functioning (Bishop et al. 2006; Gabriels et al. 2005; Militeri et al. 2002). As described above, repetitive behaviors have been distinguished into two subcategories. The first is lower order behaviors that are characterized by repetition of body or part of body movement such as stereotyped movements, repetitive manipulations of objects, and self-injurious behavior. And the second, higher order repetitive behaviors that are more complex and are more "cognitive" such as object attachments, sameness, and circumscribed interests (Bodfish 2007). Evidence has been offered that lower functioning individuals such as those with a more severe or profound intellectual disability are more likely to engage in lower order repetitive behaviors, whereas higher functioning individuals are more likely to engage in higher order repetitive behaviors that are more cognitive in nature. However, lower order and higher order repetitive behaviors have been found to co-occur (Bodfish 2007), and the distinction between higher and lower order behaviors does not hold consistently.

In lower functioning individuals, suggested age-related differences in patterns of RRBs may be less pronounced. A comorbid diagnosis of intellectual disability is associated with demonstrating more repetitive behaviors than a diagnosis of autism alone as is engaging in more atypical behaviors (Dominick et al. 2007; Esbensen et al. 2009). For the majority of RRBs, intellectual ability seems more strongly negatively correlated to

the prevalence of RRBs in older compared to younger children. Other forms of RRB such as insistence on sameness or the need for routines do not appear to be related to level of intellectual functioning (Militeri et al. 2002).

Assessment Instruments for Repetitive Behavior

While multiple assessment instruments contain items or subscales that assess for the presence of specific repetitive behaviors, a few instruments have been developed specifically for this purpose. Some of them are briefly described here.

The *Repetitive Behavior Scale-Revised* (RBS-R) is a 43-item questionnaire that was designed to assess for the breadth and severity of restricted and repetitive behaviors in autism using a 0–3 point Likert scale (Bodfish et al. 1999). The empirically validated measure includes six subscales that measure six different dimensions or conceptual groupings of restrictive and repetitive behavior. These are (a) stereotyped behavior, (b) self-injurious behavior, (c) compulsive behavior, (d) ritualistic behavior, (e) sameness behavior, and (f) restricted behavior (Bodfish et al. (2000). The current scoring for the RBS-R recommends using five empirically derived subscales based on 38 of the 43 items (Lam and Aman 2007).

The *Repetitive Behavior Questionnaire-2* (RBQ-2) is a 20-item parent questionnaire based on a four-factor model of repetitive behaviors that includes unusual sensory interests, repetitive motor movements, rigidity/adherence to routine, and preoccupation with restricted patterns of interest (Arnott et al. 2010). There is also support that items can be grouped according to two factors with motor and sensory subscales combining and rigidity and insistence on sameness subscales combining. This measure has been used to investigate the frequency of autistic-like repetitive behaviors in typically developing children (Arnott et al. 2010; Leekam et al. 2007).

The *Behavior Flexibility Rating Scale-Revised* describes 16 situations that can be rated by a parent or caregiver of a child with developmental disabilities as problematic for an individual on a

scale of 0–2. Factor analysis suggests that three factors are assessed by the scale: flexibility toward objects, flexibility toward the environment, and flexibility toward persons (Peters-Scheffer et al. 2008).

The *Behavior Problems Inventory* (BPI-01), developed by Rojahn and colleagues (Rojahn et al. 2001), is a 52-item behavior rating instrument that assesses for self-injurious, aggressive/destructive, and stereotypic behavior in individuals with intellectual and other developmental disabilities. Behaviors are rated for both frequency and severity, and information is provided by care providers. The stereotyped behavior subscale contains 25 items.

The *Autism Diagnostic Interview-Revised* (ADI-R) has been used in research as well as for assessment, diagnosis, treatment, and educational planning for individuals with an autism spectrum disorder. The ADI-R is administered as a clinical interview and can be used with children and adults. The scale consists of 93 items that focus on three domains of functioning, one of which is restricted, repetitive, and stereotyped behaviors and interests (Lord et al. 1994).

Treatment

Repetitive behaviors are currently conceptualized as a complex interaction between biology and environment so that treatment models are generally integrated and can be a combination of medication and behavioral treatments or environmental manipulations (Bodfish 2007). Three general classes of medications have received some empirical support for the treatment of repetitive or stereotyped behaviors, medications that affect the neurotransmitters dopamine such as typical and atypical antipsychotics, those that affect the neurotransmitter serotonin such as the serotonin reuptake inhibitors or SSRIs, and those that affect the opiate system, most specifically naltrexone (Bodfish 2007).

Applied behavior analysis (ABA) is the most widely supported and scientifically validated treatment for core symptoms of autism spectrum disorders, including repetitive behaviors. ABA is the application of principles of learning and

motivation to obtain changes in behavior (Myers et al. 2007). It includes functional assessment, a systematic way of understanding the purpose or function of a behavior and its contingencies of reinforcement, as well as highly structured reinforcement-based intervention methods. Behavioral intervention can focus on increasing the frequency, intensity, or range of adaptive and prosocial behaviors; decreasing the frequency, intensity, and range of repetitive, stereotyped, or self-injurious behaviors; teaching new skills; and generalizing skills across situations. Reinforcement-based techniques are generally used in behavioral treatment as are changes to the environment to remove cues that trigger repetitive behaviors or to provide environmental cues that the behavior is appropriate (Bodfish 2007; Brusa and Richman 2008).

Future Directions

While the presence of repetitive or stereotyped behaviors or restricted range of interests will likely remain a diagnostic criteria for autism in the DSM-V (American Psychiatric Association 2010), it is not likely that the presence or absence of RRBs will become a key diagnostic indicator since most RRBs can be found in other subgroups of children and even in typically developing children. It is more likely that the frequency and intensity of RRBs, the degree of distress caused when the behavior is interrupted, and the amount of dysfunction or disruption to learning that occurs as a result of the RRBs will continue to be what distinguishes children with ASDs from typically developing children or from children with other disorders. What is clear is that RRBs are an underresearched core symptom of autism spectrum disorders and can have a significant detrimental effect on learning more adaptive behaviors and result in physical injury. Additional research on the specificity of RRBs in autism spectrum disorders, how specific repetitive behaviors may change over the lifespan, and how specific individual, demographic, or environmental factors might increase the incidence of RRBs in this population is needed.

Definition

A concept introduced by, and limited to, the third edition of the *Diagnostic and Statistical Manual* (DSM-III) in 1980 to encompass individuals who once met criteria for infantile autism but no longer did so. The inclusion of this term reflected the lack

of developmental orientation in the first official definition of infantile autism in DSM-III and was meant to address the issue of developmental change. This term quickly proved unsatisfactory in many ways since the problems of most individuals with autism (or what now is termed autistic disorder) were often quite significant even if different than those they first exhibited as young children. In the following (1987) edition of DSM, the definition of autism was considerably changed to reflect a broader developmental orientation.

In some ways the concept might now seem more applicable to the small but growing number of individuals who no longer meet strict criteria for autistic disorder/autism spectrum disorder – a group that has also been termed “optimal outcome” (Fein et al. 2013). Such individuals often continue to exhibit subtle, or not so subtle, problems in social communication and learning (Suh et al. 2014; Troyb et al. 2014; Tyson et al. 2014).

Resilience in Parents of Children with Autism Spectrum Disorder

Naomi V. Ekas and Deborah Rafferty
Department of Psychology, Texas Christian
University, Fort Worth, TX, USA

Definition

Resilience is defined as a “positive adaptation within the context of significant adversity” (Luthar et al. 2000, p. 545). Rutter (1987) described resilience as a response to risk where “some people succumb to stress and adversity whereas others overcome life hazards” (p. 317). Resilience also refers to “the ability to withstand hardship and rebound from adversity, becoming more strengthened and resourceful” (Walsh 1998, 2006, p. 263). These definitions share two similarities: (1) the presence of some type of adversity or risk factor and (2) positive outcomes after exposure to risk or adversity. Moreover, inherent in each definition is the conceptualization of resilience as a *process* as opposed to a personality characteristic that an individual has (Luthar et al. 2000).

Given the multidimensional nature of the construct of resilience, it is also important to define the various components of resilience. *Risk or adversity* refers to “negative life circumstances that are known to be statistically associated with adjustment difficulties” (Luthar and Cicchetti 2000, p. 858). In the context of parents raising a child with ASD, possible risk factors may be the severity of the child’s ASD symptoms, presence of comorbid behavioral or mental health problems, the total number of children with ASD, or the quality of the marital relationship. The outcome associated with process of resilience is that of *positive adaptation*, which is defined as “behaviourally manifested social competence or success at meeting stage-salient developmental tasks” (Luthar and Cicchetti 2000, p. 858). It is also possible that the reduction or absence of negative outcomes may be another outcome of resilience (Fergus and Zimmerman 2005). Possible indicators of positive adaptation include high levels of life satisfaction, psychological well-being, and positive affect. Similarly, lower levels of depressive symptoms, anxiety symptoms, and negative affect may also be considered evidence of positive adaptation.

A key component in the process of resilience is the presence of *protective factors*. A protective factor is generally considered to be an attribute that promotes positive adaptation. For parents of children with ASD, this includes, but is not limited to, factors such as social support, personality traits, cognitive appraisals, and religiosity/spirituality. Protective factors operate in a variety of ways to enhance positive adaptation. In the *compensatory* model of resilience, the protective factor has a direct effect on the outcome of interest (Fergus and Zimmerman 2005). For example, parents of children with ASD may report higher levels of stress compared to parents of neurotypical children, but the presence of a protective factor (e.g., spirituality, social support, etc.) may help compensate for the negative effects typically associated with raising a child with ASD. This model of resilience is typically tested using multiple regression models.

In the *protective* model of resilience, the protective factors are interactive effects wherein

individuals who possess the attribute, as compared to those without the attribute, are less affected by the risk or adversity (Luthar et al. 2000). In the context of ASD, parents of children with high levels of behavior problems and greater social support may report higher levels of life satisfaction as compared to parents with low levels of social support. There are two additional protective models: (1) *protective-stabilizing* and (2) *protective-reactive*. In a protective-stabilizing model, individuals with the protective attribute display consistent levels of positive adaptation despite adversity. The protective-reactive model, in contrast, states that when adversity increases, individuals with the protective attribute will show increasing levels of positive adaptation (Luthar et al. 2000). The final set of resilience models are referred to as *vulnerability* models (Luthar et al. 2000). A vulnerability factor is one in which individuals with the attribute show higher levels of negative outcomes when faced with adversity. Parents of children with more severe ASD symptoms may report higher levels of depressive symptoms when they also report higher levels of pessimism.

Historical Background

The construct of resilience has a long history in the study of children and adolescents; however, in the context of parenting children with autism spectrum disorder (ASD), the body of research is smaller. Raising a child with autism spectrum disorder (ASD) presents unique challenges and may negatively impact parental well-being (e.g., Davis and Carter 2008). Interviews with parents of children with ASD describe being dissatisfied with the diagnostic process (e.g., Goin-Kochel et al. 2006), having to go through a period of grief after the diagnosis (Fernández-Alcántara et al. 2016), and then continuing to experience mental health problems throughout their child's life (Benson 2014). The financial burden associated with caring for a child with ASD is also substantial (Buescher et al. 2014). In general, mothers of children with ASD report lower levels of psychological well-being compared to mothers

of children with other developmental disabilities (Abbeduto et al. 2004). Thus, for a long period of time, studies of parents of children with ASD were primarily focused on examining negative outcomes, such as parenting stress and mental health problems. For example, Ekas and Whitman (2010) found that higher levels of child ASD symptom severity were associated with poorer psychological well-being in mothers of children with ASD. Davis and Carter (2008) found that children's difficulties in the domain of social relatedness were associated with increased parenting stress. Children with ASD often display comorbid behavior problems (e.g., aggression), and the presence of these behaviors consistently predicts negative outcomes in parents (e.g., Davis and Carter 2008).

Characteristics of the parents may also exacerbate negative outcomes. For example, the broad autism phenotype (BAP) is a constellation of subclinical characteristics that indicates genetic liability to ASD (Wheelwright et al. 2010). Individuals with high levels of the BAP typically have social abnormalities, a rigid personality, and pragmatic language difficulties (Hurley et al. 2007; Sasson et al. 2013). Among mothers of children with ASD, BAP symptoms are associated with elevated depressive symptoms (Ingersoll and Hambrick 2011). Pruitt et al. (2018) found that each cluster of BAP symptoms was associated with increased depressive symptoms.

The quality of parents' social relationships may also be negatively impacted when raising a child with ASD. Parents of children with ASD reported less marital satisfaction (Brobst et al. 2009), lower marital quality (Saini et al. 2015; Sim et al. 2017), and a higher divorce rates (Hartley et al. 2010) compared to parents of neurotypical (NT) children. In addition, parents of children with ASD have more severe conflict (Hartley et al. 2017b) and fewer positive couple interactions when compared to parents of NT children (Hartley et al. 2017a).

Although the aforementioned body of research suggests that raising a child with ASD is challenging, there is considerable individual variability, with some parents reporting positive outcomes (e.g., Bayat 2007; Twoy et al. 2007). In a seminal

review paper, Hastings and Taunt (2002) called for more research examining positive factors associated with parenting a child with a developmental disability, including ASD. This includes identifying factors (i.e., protective factors) that lead to positive outcomes in the context of the challenges associated with raising a child with a disability. A focus on positive adaptation is consistent with the construct of resilience in which the outcomes are expected to index competence (i.e., increase in positive outcomes or a decrease in negative outcomes). Researchers have heeded this call, and the last 10–15 years have witnessed an increase in research devoted to studying protective factors and positive adaptation among parents of children with ASD.

Current Knowledge

Researchers have identified a variety of protective factors associated with positive adaptation in parents of children with ASD. As discussed above, a protective factor may have a direct or interactive effect on adaptation in the context of risk. These protective factors are varied and include social support, characteristics of the parent, religiosity/spirituality, coping styles, and cognitive appraisals. The current state of knowledge of each of these protective factors is discussed below.

Social Support. Social support refers to the formal (e.g., government agencies) and informal (e.g., friends, family, and social media) supports that assist parents in coping with the challenges associated with raising a child with ASD. A review of the literature by Boyd (2002) summarized research showing that greater social support was associated with less stress among parents of children with ASD. Similar associations have also been found among mothers of adolescent and adult children with ASD. For example, Smith et al. (2012) found that a larger social support network predicted improvements in psychological well-being over an 18-month period. In more recent years, Tobing and Glenwick (2007) found that mothers' *satisfaction* with social support was associated with lower levels of maternal distress.

Social support can be provided by a variety of sources. Ekas et al. (2010) examined support received by friends, family, and romantic partners. Higher levels of family support (e.g., grandparents, aunts, uncles, other children) were associated with lower levels of maternal depression, stress, and negative affect among mothers of children with ASD. Of particular interest to the construct of resilience, family support was also associated with higher levels of positive affect, life satisfaction, and psychological well-being via an increase in optimism.

Social support can also be formal in nature. Some research shows that formal support services may be unhelpful or have no effect on parent outcomes (e.g., Schwichtenberg and Poehlmann 2007; White and Hastings 2004). However, one study found that families receiving government-funded services (i.e., Medicaid waivers) reported having better emotional and physical health outcomes compared to families who were not receiving services (Eskow et al. 2011). Parent education and support groups are additional forms of formal support services that show promising effects on promoting positive adaptation among parents of children with ASD (e.g., Samadi et al. 2013). Taken together, this body of research demonstrates that social support serves as a protective factor for parents of children with ASD.

Parent Characteristics. Researchers have studied whether characteristics of the parent influences their positive adaptation. Characteristics that have received empirical attention include dispositional traits such as optimism and hardiness and cognitive ways of thinking (e.g., locus of control, self-efficacy). Among parents of children with ASD, optimism has emerged as a robust predictor of outcomes. Optimism refers to the tendency to expect positive outcomes in life (Scheier and Carver 1985). Ekas et al. (2010) found higher levels of optimism were associated with increased positive affect, life satisfaction, and psychological well-being in mothers of children with ASD. In a study of Hispanic parents, mothers and fathers reported similar levels of optimism and increased optimism predicted lower levels of depressive symptoms (Willis et al. 2016). Hardiness is a personality trait that

consists of high levels of commitment, control, and challenge. Thus, during stressful situations, hardy individuals perceive the situation as interesting, they focus on the opportunity for growth, and they attempt to control the situation (Kobasa 1982). Weiss (2002) found that high levels of hardiness were associated with lower levels of depression, anxiety, and depersonalization in mothers of children with ASD. Hope is another dispositional characteristic that may serve as a protective factor. Individuals with high levels of hope are able to generate pathways to reach goals and feel that they are able to utilize these pathways (Snyder et al. 2000). For mothers of children with ASD, high levels of hope are associated with less worry (Ogston et al. 2011), less depressive symptoms (Ekas et al. 2016; Faso et al. 2013), and lower levels of loneliness (Ekas et al. 2016). Finally, recent research has begun to explore gratitude as a possible protective factor for parents of children with ASD. Similar to hope, gratitude is considered to be a character strength and refers to the tendency to be thankful for something or someone in one's life (Watkins et al. 2003). While there are no studies examining trait levels of gratitude, a study implementing a gratitude intervention found that mothers who wrote letters of gratitude reported increases in psychological well-being across the course of the intervention (Timmons and Ekas 2018).

In addition to dispositional traits, parents' ways of thinking may also serve as protective factors. For example, mothers and fathers of children with ASD who had an internal locus of control (i.e., believing that one's behavior can control events) were better able to cope with parenting stress (Siman-Tov and Kaniel 2011). Self-efficacy is an individual's confidence in their ability to succeed at tasks, goals, and challenges (Bandura 2010). Kuhn and Carter (2006) found that mothers of children with ASD with greater self-efficacy reported lower levels of depressive symptoms and stress. Parenting self-efficacy refers to a person's confidence in their ability to succeed in the domain of parenting. Rezendes and Scarpa (2011) found high parenting self-efficacy predicted less depressive and anxiety symptoms in mothers of children with ASD.

Taken together, the available body of research suggests that characteristics of the parent may confer protection against the challenges associated with parenting a child with ASD.

Religiosity and Spirituality. Decades of research in the general population show that religiosity and spirituality are associated with better psychological and physical health (Cohen and Johnson 2017). In the context of raising a child with ASD, however, these associations are less studied. Coulthard and Fitzgerald (1999) found that parents receive comfort from their religious beliefs and engagement in prayer, and these were associated with better physical and mental health outcomes. In another study, researchers examined multiple dimensions of religiosity and spirituality and found that spirituality was a better predictor of positive outcomes (Ekas et al. 2009). This is consistent with research showing that spiritual wellness (i.e., reporting high levels of meaning and purpose in life) is associated with less depressive symptoms (Graybill and Esquivel 2012). Ekas et al. (in press) found that spirituality may be efficacious because it influences the ways in which mothers interpret their child's disability. Research in this area is relatively sparse; however, the limited research suggests that spirituality may be a particularly important protective factor for parents of children with ASD.

Coping Styles. Coping refers to an individual's behavioral and cognitive efforts to manage stressful situations that exceed the individual's personal resources (Folkman et al. 1986). In stressful situations, an individual can utilize either of two coping strategies: (1) problem-focused coping, wherein an individual engages in problem-solving to prevent the situation from happening again, and (2) emotion-focused coping, in which the person tries to regulate the emotions associated with the situation. In the process of resilience, an individual's coping style may be a protective factor that is utilized on a day-to-day basis to cope with the adversity being faced.

Among parents of children with ASD, Hastings et al. (2005) identified four categories of coping strategies: (1) active avoidance, (2) problem-focused, (3) religious denial, and

(4) positive coping. In this study, mothers who engaged in problem-focused coping (i.e., planning, active coping, using social support) reported less depressive symptoms, whereas mothers who utilized active avoidance coping (i.e., substance use, behavioral disengagement, venting, and distraction) were more likely to report increased depressive symptoms. Smith et al. (2008) also found the use of problem-focused coping to be associated with greater maternal well-being. Similarly, a study of Hispanic mothers and fathers of children with ASD found that the use of positive coping strategies (e.g., planning, reframing, active coping) was associated with less depressive symptoms, whereas avoidance coping predicted greater depressive symptoms (Willis et al. 2016). In sum, the use of problem-focused coping strategies appears to promote positive adaptation among parents of children with ASD.

Cognitive Appraisals. How an individual appraises the adversity they are experiencing may impact their adaptation. When faced with adversity, individuals may engage in positive reinterpretation or attempt to find meaning in the situation. Benefit finding is a form of positive reinterpretation wherein an individual is able to find positive contribution in negative or traumatic life events (Helgeson et al. 2006). Among parents of children with high-functioning ASD, higher levels of benefit finding were associated with greater positive affect (Samios et al. 2009). Benefit finding was associated with greater family cohesion (Ekas et al. 2016) and romantic relationship satisfaction (Ekas et al. 2015). Parents who were asked to write about the benefits of caregiving reported lower anxiety scores following an intervention (Lovell et al. 2016).

Parents may also make positive reinterpretations as it relates to the contributions their child with ASD makes to their lives. The positive contributions can include the child bringing the family closer together, contributing to the parent's personal growth, the child being a source of pride, and providing happiness and fulfilment to the parent (Behr et al. 1992). Mothers of preschool children with ASD reported more positive contributions compared to fathers, and these positive

contributions were associated with lower parenting stress for mothers (Kayfitz et al. 2010). Ekas et al. (in press) found that mothers who reported greater positive contributions also reported lower levels of anxiety. In sum, how a parent appraises their child's ASD diagnosis may help to promote more positive outcomes.

Future Directions

Parents of children with ASD experience higher levels of parenting stress, which can negatively impact their well-being in several domains. While many families face these challenges, protective factors may act as a buffer to provide parents of children with ASD with the capabilities to better cope with stressors that affect their well-being. However, the scope of resilience research is limited as most of these studies focus solely on mothers of children with ASD, employ a cross-sectional design, and rely exclusively on self-reports of parent well-being. Moreover, researchers have focused almost exclusively on compensatory models and have neglected additional resilience models that examine interactive effects. As such, when examining resilience in families of children with ASD, future researchers should aim to (1) include fathers in their samples, (2) examine resilience as a process that unfolds over time and employ longitudinal study designs, (3) use multi-method studies which utilize observations of parent-child interactions, and (4) specify protective models of resilience.

Studies examining the resilience process and outcomes for fathers are scarce. Fathers of children with ASD are often not included in parenting studies despite fathers playing an important role in their child's development (Braustein et al. 2013). As a result, not much is known about how protective factors operate for these fathers, as fathers may respond to situations differently than mothers. Understanding the resilience processes for fathers of children of ASD has important implications for parent-focused interventions, as improved interventions can lead to better outcomes for both parents and their child with ASD.

Additionally, when examining resilience in the context of ASD, researchers should focus on resilience as a process that unfolds over time and, thus, utilize longitudinal methodologies. As most current research employs a cross-sectional examination of resilience, it would be difficult to determine if protective factors are more effective at different points in their child's life. By exploring resilience longitudinally, researcher may come to a better understanding of when resilience has a greater impact on parent outcomes which may provide clinicians with insight as to the best times to provide services and interventions for families of children with ASD. Researchers have exclusively used parent report to examine resilience and protective factors in parents of children with ASD. However, multi-method research may provide further insights into how protective factors and positive adaptation impact other domains of parent well-being, including the quality of parenting. Thus, it would be beneficial for future research to include additional methods, such as observations, to determine how protective factors impact the quality of parent-child interactions.

Finally, the majority of research discussed above focused on the direct impact of protective factors on parent adaptation (e.g., compensatory models of resilience). However, several resilience models describe protective factors as providing a buffer against the effects of adversity. In these models, protective factors interact with adversity to impact outcomes. Statistically, these resilience models can be tested using moderation. For example, in a study of mothers of children with ASD, Ekas and Whitman (2011) found that daily positive affect buffered the negative impact of stress but only on days of low to moderate levels of stress. Similarly, social support and coping styles moderated the association between stressful life events and negative outcomes for mothers and fathers of children with ASD (Dunn et al. 2001). Lyons et al. (2010) found that certain coping styles buffered the negative effects of child ASD symptoms severity. Further research is needed with additional protective factors, such as optimism, hope, and cognitive appraisals.

Resource Room

Karen Meers
Center of Excellence on Autism Spectrum Disorders, Southern Connecticut State University, New Haven, CT, USA

Synonyms

[Pull-out room](#); [Send-out room](#)

Definition

A resource room is defined as a separate classroom for special education outside the mainstream classroom (Volkmar and Wiesner 2009). In a resource room, students with disabilities leave the general education classroom for a specified period of time to attend the resource room and receive specialized instruction as designated by the goals and objectives outlined in their Individual Education Plans (IEP) (Mastropieri and

Scruggs 2010). The instruction may be individualized or presented in a small group format.

Respite Care

Michelle Sondra Ballan
Columbia University School of Social Work, New York, NY, USA

Definition

Individuals with ASDs typically require more intensive, individualized attention to meet specific social and communication needs as well as address behavioral excesses. As a result, family members of individuals with ASDs often report having less time for other familial and individual responsibilities and needs and report experiencing higher levels of stress. Thus, respite care is a service designed to reduce caregiver stress by affording a period of time in which the primary caregiver's role is temporarily filled by a provider

who interacts with and meets the needs of the individual. This is not only beneficial for caregiver(s) but may further develop and generalize interpersonal skills for individuals with ASDs. Unfortunately, not everyone who needs respite services receives them. Funding for respite care is allocated through general federal government, federal Medicaid, state, and private grants. A developmental disability diagnosis, documentation of IQ score, an adaptive functioning assessment, and a psychosocial assessment are typically needed with further consideration given to financial need, enrollment in other services, and availability of funds. However, not all ASDs are weighted equally. Individuals with Asperger syndrome and pervasive developmental disorder not otherwise specified may be ineligible through certain funding sources. Additionally, many grant sources are aimed solely at assisting families caring for children with ASDs. However, individual state departments on aging can be helpful with linking resources for older adults with ASDs.

The Lifespan Respite Care Act of 2006 was enacted to establish a formal program to assist family caregivers in accessing affordable and high-quality respite care. Respite can be provided at home, a day center, or a residential program and may last for a few hours, a day, or longer. Standards of respite care include meeting with a family prior to the provision of care in order to address an individual's specific needs and routines. This is essential to maintaining continuity, inherent to positive outcomes when working with individuals with ASDs.

While standards of respite care are necessary for quality of care for an individual with an ASD, the primary objective of respite is a decrease in stress levels of the caregiver, so that the individual may resume and provide care-giving responsibilities at the highest level. This may be achieved through any variety of caregiver activities. Respite breaks may be used to attend to an emergency, responsibility, or task, focusing more time in a relationship with another child or family member, or recreation, such as going to see a movie, spending time with friends, or going for a walk. Benefits of respite care for family caregivers include reduced level of stress and/or depression,

greater sense of control, improved family functioning, feeling of rejuvenation from having time to self, and more opportunities for interpersonal connectedness through social outings (Chan and Sigafoos 2001a, b; Chou et al. 2008; MacDonald and Callery 2004; McConkey et al. 2004).

Respondent Behavior

Meghan Brahm

Department of Special Education, Southern

Connecticut State University, New Haven, CT, USA

Synonyms

[Reflexive behavior](#)

Definition

Respondent behavior is the term used to describe behavior which is elicited, or brought about, by preceding stimulus events in the environment (Cooper et al. 2019).

Best known by the work of Ivan Pavlov, respondent behavior can be conceptualized as a behavior in which an organism engages in as a result of a preceding event occurring in its environment (Pear and Eldridge 1984). Also referred to as a stimulus–response paradigm, respondent behaviors primarily refer to reflexive behavior, or innate behaviors which individuals come equipped with (Cooper et al. 2019). These behaviors are believed to have a protective value for the organism and its survival (Sturmey et al. 2020). A commonly used example is the behavior of eye blinking in response to a puff of air (Sturmey et al. 2020).

In his work, Pavlov determined that respondent behaviors can come under the control of preceding stimuli. He discovered that when a tone was repeatedly presented to a dog along with a piece of meat, the dog learned to associate the tone with the meat and eventually began to salivate to the sound of the tone alone. No longer requiring the meat to be present, the tone itself gained the ability to elicit salivation behavior. Pavlov’s work, along with the work of other early behaviorists, demonstrated that reflexive behaviors, or behaviors a species is born with, are both elicited by stimuli which preceded it, and can be conditioned to occur or not occur (Pierce and Cheney 2013).

Respondent behaviors are important to consider in the context of interventions and supports for all individuals including those with autism spectrum disorder (ASD). Consider the student who has an auditory sensitivity attending PE class. Upon the PE teacher blowing their whistle (stimuli) the student may cover their ears (respondent behavior) in response to the loud sound. Through the process of respondent conditioning (see ► [Respondent Behavior](#)), it is likely that the student will begin to cover their ears (respondent behavior) upon sight of the whistle (stimuli) without the teacher having to blow it. Aiding that individual to successfully navigate PE class and instances of the whistle blowing may be an important outcome for their education, but understanding the process by which ear covering occurs is an important first step.

Respondent behaviors are often the target of interventions to increase the health, happiness, and success of individuals with ASD as well. As an

example, systematic desensitization (see ► [“Desensitization”](#)) can increase health behaviors such as completion of dental procedures (Hernandez and Ikkanda 2011). When targeting the conditioned respondent behavior and the embedded learning process, interventionists can better support individual needs (Pierce and Cheney 2013).

Response Cost

Josh Pritchard

Applied Behavior Analysis, Florida Institute of Technology, Orlando, FL, USA

Definition

Response cost is a procedure in which an individual loses a specified amount of a previously earned reinforcer contingent upon a behavior targeted for

reduction. It is often described in terms of penalties, fines, or fees and can be found in a behavior reduction plan for persons with autism.

The term and procedure originated in a basic laboratory study by Weiner (1962) to describe a contingency in which a person's response resulted in the removal of a point from an automated point counter. Since then, it has been examined in applied research and used to reduce or eliminate a large number of behavior problems across a large number of populations.

It is most frequently found as a component in token, point, and level systems, but has also been successfully used as a stand-alone procedure. Because it is a punishment procedure, it is vulnerable to the same unwanted side effects as most punishment (e.g., emotional reaction, behavior change that is situation-specific), but because it is almost always coupled with positive reinforcement, these risks can be reduced.

Response Effort

- [Effort \(Behavioral Assessment\)](#)

Response Interruption/Redirection

Bill Ahearn

The New England Center for Children,
Southborough, MA, USA

Definition

Response interruption and redirection (RIRD) is an applied behavior analytic procedure commonly implemented to treat stereotypic behavior and other responses thought to be maintained by the sensory consequences of the response (i.e., automatic reinforcement; see Rapp and Vollmer 2005). RIRD entails interrupting each instance of the target behavior and redirecting to an appropriate response (Ahearn et al. 2007). For example, if a child emits stereotypic vocalizations, then a caregiver asks the child social questions (e.g., “what’s your name?” “where do you live?” “what’s your brother’s name?”) they have readily answered in the past. Once the child answers the questions in the absence of stereotypic vocalizations, the caregiver provides brief praise and ceases asking the child questions. RIRD and a related procedure, response blocking, has produced significant change for both motoric and vocal stereotypic responses as well as with automatically reinforced self-injurious behavior. However, RIRD is not always necessary to decrease stereotypy when appropriate behavior is promoted or when stereotypy is not interfering with social functioning. When RIRD is used it should be combined with instruction and reinforcement for appropriate behavior that occurs in situations in which stereotypy is interfering. Colón et al. (2012) directly introduced verbal operant training in an effort to increase appropriate vocalizations and decrease vocal stereotypy. Vocal stereotypy persisted at clinically unacceptable levels for two

of the three participants. RIRD was then introduced and was effective at decreasing stereotypy but was unnecessary for the other participant.

Love et al. (2012) offered noncontingent access to matched stimulation (toys that produced sound) as a means of providing an alternative activity while evaluating whether a decrease in vocal stereotypy would occur concomitantly. Matched stimulation and RIRD were then compared as a combined package and alone. RIRD was necessary to decrease vocal stereotypy to clinically significant levels and appropriate behavior continued to occur when RIRD was used while matched activities were present. Although RIRD has been shown to be an effective procedure, Duffy-Cassella et al. (2011) and Miguel et al. (2009) suggested that RIRD may require effortful treatment application particularly if an individual initially engages in high rates of stereotypy. However, two studies suggest that once RIRD has been implemented with high levels of integrity (i.e., correctly and for each instance during the times/situations in which stereotypy is being treated) that not every instances of stereotypy needs to be redirected for a treatment effect to be maintained (Ahrens et al. 2011; Colón and Ahearn 2019). Also, Sivaraman and Rapp (2019) examined the subsequent effects of RIRD when the treatment was no longer in place and found that longer exposure to the procedure, 20 min versus 5 min, was associated decreased stereotypy persisting for a short period of time.

Restricted and Repetitive Behaviors and Sleep Disturbances in ASD

Rachel Hundley¹ and Beth Malow²

¹Division of Developmental Medicine,
Department of Pediatrics,
Vanderbilt University Medical Center,
Nashville, TN, USA

²Sleep Disorders Division,
Department of Neurology,
Vanderbilt University Medical Center,
Nashville, TN, USA

Definition

Sleep problems may contribute to, and be exacerbated by, specific behavioral challenges in individuals with ASD, including restricted and repetitive behaviors.

Historical Background

Sleep problems are common in childhood and throughout the lifespan. Approximately 20–30% of typically developing children experience sleep difficulties, with the most common problems including difficulty falling asleep and staying asleep. Among adolescents and adults, sleep problems are more often labeled as insomnia (Meltzer and Mindell 2014). Population-based studies of adults conducted around the world suggest that approximately 30% of adults experience one or more symptoms of insomnia. Sleep problems occur even more frequently in children and adults with neurodevelopmental and psychiatric comorbidities (Krakowiak et al. 2008; Richdale and Schreck 2009).

Most of the research on sleep disturbance in Autism Spectrum Disorder (ASD) has been conducted on child and adolescent populations. Children with ASD are more likely to have sleep problems than are children in the general population, with prevalence estimates ranging from 50–80% (Couturier et al. 2005; Krakowiak et al. 2008; Richdale and Schreck 2009). Parents of children with ASD are more likely to report that their child resists going to bed, has problems falling asleep, has restless sleep, experiences nighttime or early morning awakenings, and sleeps less overall. Children with ASD also have higher rates of parasomnias, such as night terrors or talking and walking during sleep (Richdale and Schreck 2009). Sleep problems present significant and unique challenges for children with ASD and their families. As sleep is critical for normal brain development, sleep problems can reduce a child's ability to learn. They may also increase rates of challenging and repetitive behavior, making it more difficult for a child to cooperate with daily routines, participate in the community, and interact with others. The behavioral cascade of sleep disturbance may have long-term detrimental effects on a child's ultimate level of functioning and ability to develop relationships (Meltzer and Mindell 2014; Veatch et al. 2017). Sleep problems in children with ASD also contribute to maternal stress and maternal mental health (Hodge et al. 2013).

Current Knowledge

Causes of sleep abnormalities within ASD are assumed to be multifactorial, encompassing many possible biological, medical, psychological, and behavioral mechanisms. Biological correlates may include disruption in the sleep-wake cycle (circadian rhythms) and in melatonin production and regulation (Veatch et al. 2015). Medical contributors to sleep disturbance may include epilepsy, gastrointestinal distress, and pharmacological side-effects (Hollway and Aman 2011). Over the last two decades, investigators have examined a wide variety of developmental, emotional, and behavioral correlates of sleep

disturbance. Areas of interest have included the association of sleep disturbance to age, intellectual, language, and adaptive skills, psychiatric comorbidities, overall intensity of core features of ASD, and specific symptoms within ASD (Hollway et al. 2013).

Initial research on sleep problems in ASD used subjective measures, such as parent or self-report questionnaires and sleep diaries. Commonly used assessment tools have included: The Children's Sleep Habits Questionnaire (CSHQ; Owens et al. 2000), the Family Inventory of Sleep Habits (FISH; Malow et al. 2009), and the Behavioral Evaluation of Disorders of Sleep (BEDS; Schreck et al. 2003). Increasingly, investigators have paired parent- and self-reports with direct measures of sleep, including actigraphy, polysomnography, and other systems of recording sleep behaviors and physiologic activity (Meltzer et al. 2012). Studies using objective measures have largely confirmed parent's report of delayed sleep onset, fragmented sleep, reduced sleep efficiency, and decreased sleep length (Goodlin-Jones et al. 2008).

Cross-sectional and longitudinal designs have been used to better understand the onset and developmental course of sleep problems in ASD. As compared to their typically developing peers, children with ASD have shown sleep disturbance as young as 30 months of age, by parent-report (Humphreys et al. 2014). Longitudinal research has shown that sleep problems typically persist from childhood into adolescence and an emerging body of literature demonstrates that sleep problems may last into adulthood (Goldman et al. 2012; Baker and Richdale 2015). Results of self-report, sleep diaries, and actigraphy suggested that cognitively able adults with ASD take longer to fall asleep, have reduced sleep efficiency, and feel less refreshed after sleep than well-matched controls (Baker and Richdale 2015).

It is established that individuals with intellectual disability experience more sleep problems than their typically developing peers (Richdale et al. 2009); however, the association among sleep, IQ, adaptive skills, and language function in children with ASD appears complex and is not

yet well understood. In one review, approximately 40% of studies found associations between IQ and sleep and 60% did not (Hollway and Aman 2011). Similarly, findings for language and adaptive skills have been mixed (Veatch et al. 2017).

Severity of core ASD symptoms, including problems with social communication and the presence of restricted and repetitive behaviors, is clearly and significantly associated with sleep disturbance. Parent ratings of children with more severe total ASD symptoms indicated more sensitivity to nighttime sleeping environments, more frequent awakenings, and more overall sleep disturbance (Giannotti et al. 2008; Schreck et al. 2004; Mayes and Calhoun 2009). In a seminal review of the correlates of sleep disturbance in ASD, Hollway and Aman (2011) postulated a bidirectional theoretical framework in which core symptoms of ASD represented vulnerability factors that increased children's risk of insomnia when presented with environmental stressors. Features of ASD increased the possibility for maladaptive coping mechanisms, such as internalizing and externalizing behavioral problems, and decreased sleep. Specifically, as ASD symptoms increased across social communication and behavior domains, children were theorized to have higher likelihood of an anxiety-related response to stressors. Because reduced sleep has been shown to disrupt daytime behavior, the model maintained a bidirectional component.

Within diagnostic features of ASD, higher rates of social impairment have been associated with poor sleep quality and shorter sleep duration among children and adolescents (Phung and Goldberg 2017; Veatch et al. 2017). The association of sleep disturbance to specific problems in developing interpersonal peer relationships has been observed across studies. Peer relationships provide an important context for development for all children. As developing and maintaining social relationships is an area of increased vulnerability for children with ASD, interventions that improve sleep may have downstream effects on social outcomes. For example, children who are less irritable, or sleepy, will be able to make gains in therapy related to social interactions and to interact more positively with others.

Though restricted, repetitive behaviors (RRB) also represent a core symptom domain within ASD, a growing body of literature has demonstrated that challenges associated with RRB may contribute to sleep disturbance over and above general ASD severity. Poor sleepers with ASD have shown higher rates of stereotypy and screaming during the night (Schreck et al. 2004), repetitive sensory motor behaviors (Hundley et al. 2016), compulsive and ritualistic behavior (Goldman et al. 2009), and aggressive behavior (Park et al. 2012). Sensory over-responsivity has also been correlated with multiple sleep problems (Mazurek and Petroski 2015). Sensory problems at bedtime may manifest as hyperarousal and excessive or negative responses to aspects of the nighttime sleeping environment.

Best practices for treating sleep disturbance in children with ASD often begin by addressing the behavioral aspects of sleep (Malow et al. 2012; Souders et al. 2017). Behavioral interventions have been identified as a first-line approach in treating sleep problems. Studies encompassing parent training through a variety of formats including handbooks, group education, and in-person and telephone-based individual sessions have all been successful at reducing time to fall asleep and increasing total length of sleep. Training content has largely included principles of sleep hygiene, such as consideration of a calm and comfortable sleeping environment, provision of ample light in daytime – particularly in the early morning upon awakening, avoiding naps, reducing caffeine, and a consistent bedtime routine that is carefully planned to move more stimulating activities to earlier in the evening and calming activities closer to bedtime. Bedtime passes that are paired with rewards for remaining in bed have been useful with older children (Moore et al. 2007). Detailed information on behavioral treatment of sleep in ASD is provided in additional references (Katz and Malow 2014; Malow et al. 2014).

Medications are commonly used to improve sleep. Melatonin is the most studied and utilized choice for children with ASD (Hollway and

Aman 2011b; Malow et al. 2016). Multiple studies have documented an association between higher rates of repetitive behaviors and the use of medication for sleep (Abel et al. 2018; Malow et al. 2016).

Future Directions

As many individuals are diagnosed with ASD, it is increasingly important for medical and behavioral health providers to be aware of the high rates of sleep difficulties in children, adolescents, and adults with ASD, to assess for these problems, and to be facile with evidence based medical and behavioral interventions. As interventions for sleep are applied within homes and families, it is important to consider family-based, collaborative, and culturally sensitive approaches to treatment (Bellesheim et al. 2019). Encouraging family-driven goals and allowing for flexibility within standardized protocols may improve treatment adherence and results. While most research has centered on care provided to families in academic health centers, behavioral sleep education provided to parents by therapists in community settings is showing promise (MacDonald et al. 2019). Other approaches include the use of telehealth or mobile phone apps (Corkum et al. 2018). Future longitudinal research may seek to better understand the bidirectional association of sleep problems to development, health, and general well-being. Further intervention studies are needed to clarify the types of behavioral treatment that most effectively address specific sleep problems at different ages and developmental and language levels. Similarly, it should be recognized that individuals with ASD will have varying behavioral needs.

Restricted Interest

Yael Kimhi

Education, Levinsky College of Education, Tel-Aviv, Israel

Synonyms

[Limited interests](#); [Restrictive interests](#)

Definition

A limited set or limited number of interests and/or activities. Restricted and repetitive patterns of behaviors comprise one of the diagnostic criteria for autism spectrum disorders (APA 2013). The restricted interests may be simple motor stereotypies (i.e., lining up objects), echolalia (i.e., repetition of words or phrases), insistence on sameness (i.e., non-varied food or clothes), inflexible adherence to routines (i.e., same routes or schedules), highly restricted fixated interests (i.e., a narrow or limited range of items that hold the individual's interest), and hyper- or hypo-activity to sensory input (i.e., such as sounds, textures, lights, smell) (APA 2013).

Restrictive and repetitive behaviors (RRBs) in ASD can range from extreme and obvious to subtle and infrequent (Bernier 2014). Restricted interests can be seen in children as young as 17–37 months old (Matston et al. 2009). They are pervasive and can be associated with persistent interference with the social, communicative, and adaptive functioning in individuals with ASD. The interference with or interruption of the restricted interests can evoke challenging behaviors (i.e., outbursts, tantrums, severe anxiety, etc.) and can often cause significant challenges for the individual with ASD and his/her family (Stratis and Lecavalier 2013). Notwithstanding, by using

the individual's interest to improve task performance, RRBs can be used as intrinsic reinforcement and motivating rewards (Vismara and Lyons 2007). High levels of restricted interests were found to be associated with less severe symptoms of depression in individuals with ASD, suggesting that restricted interests may be an alleviating factor against the development of depression in ASD (Stratis and Lecavalier 2013). Furthermore, routines have been found to present an individual with ASD a sense of stability, predictability, and consistency, which can minimize their risk for adjustment problems (Stoppelbein et al. 2016).

Assessment of restricted behaviors: the Repetitive and Restricted Behavior Scale (RBS; Bodfish et al. 1999) and the Repetitive and Restricted Behavior Scale-Revised (RBS-R; Bodfish et al. 2000; Lams and Aman 2007) are scales specifically designed for the assessment of RRBs. The Autism Diagnostic Observation Schedule (ADOS; Lord et al. 1999) enables observation of RRBs during the variety of structured and play-based activities. The Autism Diagnostic Interview-Revised (ADI-R; Le Couteur et al. 2003) is used to gather information through parent interview and includes 13 questions that are grouped in the “interests and behaviors” category.

Retrieval of Information

Amy Heberle
Clinical Psychology, University of
Massachusetts, Boston, MA, USA

Synonyms

Recall; Recognition

Definition

The process by which memories of events or information are recalled is known as retrieval of information. Retrieval of information is one of three processes involved in long-term memory; the other two processes are encoding and storage. Two kinds of information may be stored in the brain: episodic and semantic. Episodic memories are memories of personal events, whereas semantic memories contain general knowledge that a person has learned about the world. Together, episodic and semantic memories are known as explicit (or conscious) memories. The brain also stores unconscious memories (sometimes called implicit memories). These memories allow humans to perform tasks without having to think about how to do them (e.g., writing, bicycling). Explicit memories may be retrieved via recognition or recall. Recognition occurs when a present experience is automatically associated with a stored memory. For example, answering a multiple-choice question on a test may involve recognition. Recall involves re-accessing a memory that has not been directly triggered by a present experience. Responding to a short answer question on a test is an example of a task that requires recall.

Some individuals with autism appear to have certain memory-related deficits. For instance, impairments in working memory (the capacity to store information that the brain is actively processing) and short-term memory (the capacity to store information for a brief period of time) have been found. The pattern of deficits and strengths observed in individuals with autism may be similar to that of individuals with lesions in the frontal lobe of the brain. With regard to retrieval of information, individuals with autism may have deficits that are specific to certain types of information. For instance, individuals with autism may have difficulty retrieving information from episodic (or personal experience) memory but not from semantic (or general information) memory. They may also show deficits in comparison to non-autistic individuals in recall of semantic

information that contains contextual information (e.g., a sentence as opposed to a random string of words).

It is important to note that the profile of strengths and deficits in the ability to retrieve stored information will vary across individuals with different levels of functioning and different comorbidities. Intellectual disabilities may have a significant effect on memory functioning. In assessing recall and recognition in individuals with autism, researchers and clinicians must take note of the type of information involved (e.g., social vs. nonsocial material), as performance may differ based on the content of the information to be recalled. Retrieval of information may also be dependent on the context of learning or of assessment, with variation across individuals on the ideal context for obtaining optimal performance in each area of memory.

Retrospective Infant Video Analysis

Karen Toth

Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, USA

Definition

Autism, once a relatively rare disorder, is now seen in as many as 1 in 88 children (Baird et al. 2006; Centers for Disease Control and Prevention CDC 2012). There is considerable interest in identifying the earliest emerging signs and symptoms of autism so that interventions can be developed to ameliorate or even prevent the disorder. Retrospective home videotape analysis is one methodology that has been used to explore the early behaviors of children who were later diagnosed with autism. This technique, which involves careful coding of behaviors from home videotapes, has been used to study communication, social, and sensory motor development in infants as young as the first 6 months of life. Findings have revealed impairments evident at a very early age in children who later meet criteria for an autism spectrum disorder (ASD; see Yirmiya and Charman 2010, for a review).

Historical Background

Autism spectrum disorder (ASD) is among the most complex and heritable of neurodevelopmental disorders. The phenotype comprises a wide range of behavioral syndromes and trajectories as diverse as the underlying risk factors and etiological mechanisms for ASD (Geschwind 2008). As such, it has been difficult to characterize a specific early symptom cluster for this disorder. Attempts to do so have accelerated over the past two decades with the aim of informing the development of early interventions that can ameliorate or even prevent the course of this disorder.

A number of novel approaches have been developed to augment retrospective parent report and shed light on the earliest emerging signs and symptoms of autism. One such approach has been to examine home videos taken prior to the child's diagnosis. The advantages of this methodology include the opportunity for trained observers blind to the child's later diagnosis to examine specific behaviors over time and across varying, naturally occurring contexts. However, there is a lack of standardization with this methodology and an inherent bias that occurs when only certain behaviors and contexts are chosen by families to be videotaped. Nevertheless, these studies have elucidated a number of behaviors that distinguish children later diagnosed with autism from children with delayed and typical development, as early as within the first 6 months of life.

Current Knowledge

The first studies of home videotapes in the early 1990s involved very small samples and typically developing children as controls. Impairments identified prior to 12 months of age included less goal-directed action (Losche 1990) and deficits in social interaction including reduced eye contact, social smiling, and facial expressions as compared to typically developing infants (Adrien et al. 1991, 1993). Following these studies was a group of studies that used first birthday parties to semi-standardize the context across participants. These studies found that less eye contact and less frequent response to name distinguished 12-month-old children later diagnosed with autism from 12-month-old infants with typical *and* delayed development (Osterling and Dawson 1994; Osterling et al. 2002) and that these same two indicators distinguished children later diagnosed with autism from typically developing infants as young as 8–10 months of age (Werner et al. 2000). Werner and Dawson (2005) also found early differences between children with and without regression who were later diagnosed with autism. Specifically, this study provided evidence of intact abilities at 12 months of age in

children with regression who were later diagnosed with autism, as is often reported by parents, as compared to children without regression who showed deficits in joint attention and communication. By 24 months, children both with and without regression showed deficits compared to typically developing children in use of eye contact, response to name, and communicative skills such as gesture, words, and vocalizations. Mars, Mauk, and Dowrick (1998) were the first to extend this technology to separately examine children later diagnosed with PDD-NOS as compared to children later diagnosed with autism. They found fewer joint attention deficits in the PDD-NOS group between 12 and 30 months of age.

Home video studies over the past decade have broadened to include a wider range of behaviors including pretend play, sensory behaviors, intersubjective behaviors, and motor behaviors. Maestro et al. (2001) examined early precursors to theory of mind abilities in infants in the first 6 months of life and found that children later diagnosed with autism showed deficits in anticipating another's aim and imitation compared to typically developing infants and poorer symbolic skills between 6 and 24 months. Maestro et al. (2002, 2005, 2006) went on to show that infants with autism over the first year of life demonstrated increasing attention away from social stimuli and toward objects, and this held true whether or not the children experienced a clinical regression. More recently, abnormalities in motor activity (more fidgety movements) distinguished children later diagnosed with autism vs. typically developing children (Phagava et al. 2008), and in the first 5 months of life infants with autism demonstrated lower levels of symmetry in motor movements as compared to infants with delayed and typical development (Esposito et al. 2009). However, Ozonoff et al. (2008) found more early abnormalities in motor behaviors in children with delayed development than in children with autism, indicating that movement abnormalities may be a consequence of general developmental delay rather than specific to autism.

In sum, while comparison groups, behaviors targeted, and age ranges vary across home videotape studies, taken together, results indicate the

presence of abnormalities in social communication functioning in the first year of life in children with ASD. More specifically, in the first 6 months of life, deficits in person-person interactions (dyadic, intersubjective) and reduced attention to social stimuli are apparent in infants with autism. By the end of the first year, triadic impairments (person-object-person) are evident, including decrements in joint attention, response to name, expression of emotions, and motor movement abnormalities. While retrospective home videotape methodology has provided information on early emerging behaviors and deficits in children later diagnosed with autism, it does not tell us how many children show these same early signs and do *not* go on to develop autism. For those data, a number of prospective studies that include children at risk for autism (e.g., infant siblings of children with autism) as well as large-scale pediatric screening studies have been conducted in recent years (see Yirmiya and Charman 2010, for a review).

Future Directions

To gain a better understanding of early markers specific to children who develop autism, future research will need to combine various methodologies as well as genetic, environmental, brain, and behavioral factors; this approach will shed light on the etiology of autism as well as the trajectories of the various phenotypes found in this complex neurodevelopmental disorder.

Rett Syndrome

D. O. Alvi Azad

Yale Child Study Center, The Edward Zigler Center in Child Development and Social Policy, Yale University, New Haven, CT, USA

Synonyms

Cerebroatrophic hyperammonemia; Rett's disorder

Short Description or Definition

Rett syndrome is a progressive X-linked dominant neurodevelopmental disorder which affects females almost exclusively. Rett syndrome displays a characteristic pattern of cognitive and functional stagnation and subsequent deterioration. Postnatal brain growth and neuronal development are highly impacted, and Rett syndrome represents one of the most common causes of

mental retardation in females second only to Down syndrome. Stereotypic hand movements, typically at midline, are one of the most prominent symptoms. Other characteristics of this disorder include a loss of spoken language and loss of or impaired ambulation (abducted gait). Seizure activity and scoliosis or kyphosis are common comorbid disorders.

Throughout the world teams of scientists have worked to gain a better understanding of Rett syndrome, attempting to identify the cause and pathophysiology of the disorder. A major breakthrough occurred in 1999 when Dr. Amir, a scientist at Baylor University (Huston, TX), discovered that Rett syndrome is caused by a mutation of the *methyl-CpG-binding protein 2 (MECP2)* gene. Rather than an inherited disorder that is passed on from one generation to the next, Rett syndrome is typically caused by a sporadic mutation of the *MECP2* gene. In most cases, the damaged copy of *MECP2* can be traced to the paternal allele. The incidence of recurrence in a family is less than 1%.

There are a number of atypical forms of Rett syndrome including individuals with developmental delays prior to regression or who lack the initial period of normal development (congenital variant) or who display an early psychomotor delay but without regression until school age (delayed onset variant), a group whose supportive characteristics do not appear until late childhood (atypical or “forme fruste”), those with a family recurrence (familial variant), and those who have retained some speech (“preserved speech variant”).

While Rett syndrome remains a clinical diagnosis, the link with *MECP2* has made DNA testing and confirmation possible for affected individuals and their families. To date, approximately 95% of girls exhibiting Rett symptoms have one of the over 200 currently identified *MECP2* mutations.

Rett syndrome is the first human disease found to be caused by defects in a protein involved in the regulation of gene expression through its interaction with methylated DNA. As such, Rett syndrome could hold the key to our understanding of a number of human disorders ranging from some forms of learning disability to autism.

Categorization

The diagnostic criteria for Rett syndrome initially developed in the mid-1980s (Hagberg et al. 1985; The Rett Syndrome Diagnostic Criteria Work Group 1988) and revised in 2002 (Hagberg et al. 2002) and have been recently revised once again (Neul et al. 2010). The fourth edition (revised) of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) has included Rett syndrome (termed Rett’s disorder) as a subcategory of pervasive developmental disorder. The DSM-IV-TR diagnostic criteria for 299.80 Rett’s disorder generally coincide with those initially proposed by The Rett Syndrome Diagnostic Criteria Work Group (1988). The DSM-IV-TR criteria, however, differ in some significant ways from the most recent revision of the diagnostic criteria developed by members of the Rett Search Clinical Research Consortium, an international panel of experts convened by the International Rett Syndrome Association (2010). For example, the DSM-IV-TR indicates “apparently normal psychomotor development through the first 5 months after birth,” whereas Neul and his associates (2010) suggest that “mild generalized hypotonia and other previously reported subtle developmental alterations during the first 6 months of life are common in Rett syndrome.” Deceleration of head growth between 5 and 48 months of age is a necessary criterion within the DSM-IV-TR. The revised IRSA diagnostic criteria, on the other hand, have removed deceleration of head growth as a criterion. The members of the consortium simply indicate as a note that physicians should consider Rett syndrome as a diagnosis when postnatal deceleration of head growth is observed. They did so as an increasing number of individuals with Rett syndrome have a normal head size. The DSM-IV-R requires a loss of social engagement early in the course of the disorder (that may subside to some degree later). No such requirement is found in the new IRSA criteria.

The new IRSA criteria also provide diagnostic criteria for atypical or variant forms of Rett syndrome, while no such criteria are considered in the DSM-IV-R. Individuals must display at least 2 of the 4 main criteria for classical Rett syndrome and

5 of the 11 supportive criteria to qualify for the atypical diagnosis (see Table 1). The supportive criteria provided by the IRSA criteria are not required for a diagnosis of typical or classic Rett syndrome. The DSM-IV-TR includes EEG abnormalities, seizures, nonspecific brain imaging abnormalities, and severe or profound mental retardation (Axis II) as associated features and disorders. Thus, the two sources differ in regard to associated and supportive features of the disorder. Moreover, the current DSM-IV-TR criteria fail to indicate exclusionary criteria that are critical for differential diagnosis.

Epidemiology

Persons with Rett syndrome have been reported to exist in most countries of the world. Thus, Rett syndrome does not seem to be a particularly rare disorder, and it is more or less universal. The prevalence of the Rett syndrome has been studied, based upon the Swedish registry for mental retardation and surveys of neuropsychiatrists, in a part of southwestern Sweden (Hagberg 1985). The prevalence was about 1 per 15,000 live female births. In their study of 5,400 consecutive referrals to the pediatric neurology center in western Scotland et al. (1985) identified 19 cases of Rett syndrome. The resulting prevalence rate was very similar to that reported by Hagberg (1985), 1 per 12–13,000 females (Kerr and Stephenson 1986).

A prevalence study was conducted within the United States by a number of researchers at the Baylor College of Medicine (Kozinetz et al. 1993). The study employed the Texas Rett Syndrome Registry and explored females aged 2–18 years, and was the first with a large ethnic mix that would allow an exploration of racial/ethnic group-specific prevalence of Rett syndrome. A prevalence estimate of approximately 1 per 22,800 live female births was reported with no significant differences in prevalence estimates by race/ethnicity (African American, Caucasian, and Hispanic). This estimate is lower than that reported in earlier studies, suggesting the prevalence of Rett syndrome has perhaps been overestimated.

Natural History, Prognostic Factors, Outcomes

During normal human development, a large number of genes are expressed in a tissue-specific manner. That is, the gene must only function in the creation of specific cells. Many of these genes are needed during critical periods of central nervous system (CNS) development, and then their expression must be turned off. Other genes are required only after birth, and turning these genes on and off at appropriate times are critical for normal and proper development. The *MeCP2* gene encodes the development of the transcriptional silencing *methyl-CpG-binding protein 2*. This protein plays an important role in the “silencing” of various genes during CNS development. The mutations in the *MecP2* gene in Rett syndrome result in a failure to produce the *MecP2* protein. Thus, the genes that *MeCP2* would normally silence continue to engage in ongoing transcription. The number and nature of the genes for which *MeCP2* is meant to suppress throughout the genome is as yet unknown (Singer and Naidu 2001), although there is reason to believe these genes regulate the development and mature function of the brain and central nervous system (Shahbazian and Zoghbi 2002).

Numerous different mutations of the *MeCP2* gene have been identified in individuals with Rett syndrome. Some researchers suggest that the specific type of mutation in the *MECP2* gene affects the type and severity of symptoms of Rett syndrome. Studies are now underway to understand each mutation that may cause the features of Rett syndrome, and how these mutations might change the features of the syndrome. Investigators are trying to find other genetic switches that operate in a similar way to the *MeCP2* protein. Once they discover how the protein works and locate similar switches, they may devise therapies that can substitute for the malfunctioning switch. Another outcome might involve manipulating other biochemical pathways to compensate for the malfunctioning *MECP2* gene, thereby preventing progression of the disorder. Gene therapy to achieve regulated expression of a normal

Rett Syndrome, Table 1 Diagnostic criteria for Rett syndrome and Rett's disorder

Diagnostic criteria established by Neul et al. (2010)^a Consider diagnosis when postnatal deceleration of head growth is observed Required for typical or classical Rett syndrome 1. A period of regression followed by stabilization^c 2. All main criteria and all exclusion criteria 3. Supportive criteria are not required, although often present in typical RTT Required for atypical or variant RTT 1. A period of regression followed by recovery or stabilization^b 2. At least 2 of the main 4 criteria, 3. 5 out of 11 supportive criteria Criteria Main criteria 1. Partial or complete loss of purposeful hand skills 2. Partial or complete loss of acquired spoken language^d 3. Gait abnormalities: impaired (dyspraxic) or absence of ability 4. Stereotypic hand movements such as hand-wringing/squeezing, clapping/tapping, mouthing, and washing/rubbing automatisms Exclusion criteria for typical RTT 1. Brain injury secondary to trauma (peri- or postnatally), neurometabolic disease, or severe infection that causes neurological problems^e 2. Grossly abnormal psychomotor development in first 6 months of life^f Supportive criteria for atypical RTT^g 1. Breathing disturbances when awake 2. Bruxism when awake 3. Impaired sleep pattern 4. Abnormal muscle tone 5. Peripheral vasomotor disturbances 6. Scoliosis/kyphosis 7. Growth retardation 8. Small cold hands and feet 9. Inappropriate laughing/screaming spells 10. Diminished response to pain 11. Intense eye communication – “eye pointing”	DSM-IV-TR Rett's disorder^b Necessary criteria A. All of the following: 1. Apparently normal prenatal and perinatal development 2. Apparently normal psychomotor development through the first 5 months after birth B. Onset of all of the following after the period of normal development: 1. Deceleration of head growth between ages 5 and 48 months 2. Loss of previously acquired purposeful hand skills between ages 5 and 30 months with subsequent development of stereotyped hand movements (e.g., hand-wringing and hand-washing) 3. Loss of social engagement early in the course (although often social interaction develops later) 4. Appearance of poorly coordinated gait or trunk movements 5. Severely impaired expressive and receptive language development with severe psychomotor retardation Associated features and disorders 1. Severe or profound mental retardation (axis II) 2. Increased frequency of EEG abnormalities and seizure disorders 3. Nonspecific brain imaging abnormalities

^cBecause MECP2 mutations are now identified in some individuals prior to any clear evidence of regression, the diagnosis of “possible” RTT should be given to those individuals under 3 years old who have not lost any skills but otherwise have clinical features suggestive of RTT. These individuals should be reassessed every 6–12 months for evidence of regression. If regression manifests, the diagnosis should be changes to definite RTT. However, if the child does not show any evidence of regression by 5 years, the diagnosis of RTT should be questioned

^dLoss of acquired language is based on best-acquired spoken language skill, not strictly on the acquisition of distinct words or higher language skills. Thus an individual who had learned to babble but then lost this ability is considered to have a loss of acquired language

^eThere should be clear evidence (neurological or ophthalmological examination and MRI/CT) that the presumed insult directly resulted in neurological dysfunction

^fGrossly abnormal to the point that normal milestones (acquiring head control, swallowing, developing social smile) are not met. Mild generalized hypotonia or other previously reported subtle developmental alterations during the first 6 months of life is common in RTT and do not constitute an exclusionary criterion

^gIf an individual has or ever had a clinical feature listed it is counted as a supportive criterion. Many of these features have an age dependency, manifesting and becoming more predominant at certain ages. Therefore, the diagnosis of atypical RTT may be easier for older individuals than for younger. In the case of a younger individual (under 5 years old) who has a period of regression and >2 main criteria but does not fulfill the requirements of 5/11 supportive criteria, the diagnosis of “probably atypical RTT” may be given. Individuals who fall into this category should be reassessed as they age and the diagnosis revised accordingly

MECP2 gene is also under study in animal models.

Neuropathological studies have been conducted in Rett syndrome that may assist in gaining a better understanding of how ineffective *MeCP2* activity produces Rett syndrome. While individuals with Rett syndrome are typically small for their age, only the brain weighs less than expected for the height and weight of the individual. This supports the view that the *MeCP2* gene appears to have its greatest impact on “downstream” genes that code for the development and mature function of brain tissue. Accumulated autopsy studies suggest that the brain of the individual with Rett syndrome weighs significantly less than that of controls matched for both age and height. The decrease in brain size and weight appears to begin after birth (in most cases), starting at 3–4 months of age. Brain size and weight appear to stabilize in later childhood and the absence of markers for significant degenerative disorder supports the idea that the decreased brain size is the result of arrested brain development (Duncan Armstrong 2001).

The concentrations of two major brain gangliosides, GD1a in frontal gray matter and GD1b in temporal gray matter, appear to be lowered selectively in the cerebral cortex and cerebellum in girls with Rett syndrome (Lekman et al. 1991). The ganglioside GD1a is thought to play an important role in synaptogenesis since it is prominent in synaptic membranes, and high concentrations are reported during the time when nerve ending growth and synapse formation are most intense (25th fetal week until age 2 years). Ganglioside GD1b is rich in axons and accrues more slowly, reaching maximum concentration at age 20 years. The reduction in GD1a would help explain the pathogenic findings of decreased dendritic arborization reported by Armstrong (1992).

Synapses within the cerebral cortex, basal ganglia and brainstem responsible for movement and breathing employ the use of the excitatory amino acid neurotransmitter glutamate. Glutamate-mediated neurotransmission appears to be disrupted in persons with Rett syndrome (Lappalainen and Riikonen 1996).

Clinical Expression and Pathophysiology

Individuals with classical Rett syndrome exhibit a characteristic course of development. Prenatal and perinatal histories of these persons are generally unremarkable. While minor pre- and perinatal problems (e.g., mild hypotonia, tremulous neck movements, a low intensity of interpersonal contact, and abnormal hand use and language development) can be identified retrospectively in as many as 80% of the girls, it is unlikely that these mild symptoms would be detected as relevant even with detailed neurologic or developmental assessment. This apparently normal period of development is followed by a slowing or cessation of the acquisition of developmental milestones.

Hagberg and Witt-Engerstrom (1986) proposed a staging system to facilitate the characterization of the disorder patterns and profiles from infancy through adolescence. Their system suggests four clinical stages and was derived from a synthesis of clinical observations over the years in 50 Swedish cases of Rett syndrome. The purpose of the staging system is to provide average guidelines for stage patterns thought to be of use when confronted with the diagnostic problems resulting from the complex symptomatology and longitudinal profile of the condition. The four stages include early onset stagnation phase, rapid destructive stage, pseudostationary stage, and late motor degeneration stage. This staging system has gained general acceptance; however, the names assigned to each stage have been criticized (e.g., Trevathan and Naidu 1988), and the stages are commonly referred to simply by number. The symptoms and features of each of the four stages are as follows:

- *Stage 1* (onset 6–18 months) The clinical profile at this stage suggests a deterioration or at least a general slowing down (stagnation) of motor development. Hypotonia is typically noted. Deviation from normal development is often compensated for or hidden, in part, by the rapid developmental speed of infancy. Thus, additional gross motor abilities often are learned during this stage, even as others are lost, but are delayed in their appearance. The

symptoms of stage 1 are nonspecific and are not predictive of subsequent deterioration.

- *Stage 2* (onset 1–3 years) During this stage the syndrome becomes significantly more pronounced as the children lose previously acquired abilities. In most individuals, a relatively well-demarcated period of rapidly declining social interaction, stagnation or loss of acquired cognitive abilities, and loss of purposeful hand use and speech is evident. Stereotyped movements become a prominent symptom. The intellectual functioning of the girl with Rett syndrome during this stage is generally reported to fall within the severe to profound range of mental retardation. Ataxic/aprasic gait abnormalities are observed in ambulatory girls. Also, during the time the child is awake, she may display aberrant breathing patterns. Hyperventilation and respiratory pauses (generally lasting 30–40 s) are most common. Seizure activity is present in approximately one-fourth of the girls during this stage. Sleep abnormalities including delayed sleep onset and increased night awakenings are manifested by more than three-fourths of the girls.
- *Stage 3* (onset 2–10 years) Persons with Rett syndrome generally demonstrate diminishing autistic symptomatology and improved social interaction during this period. They appear to be more aware of their surroundings and seem to make attempts at using residual functional skills. Communication skills are reported to improve with better interaction. Some girls employ eye pointing, babbling, or even word pieces to signal communicative intent. Seizures occur in up to 80% of the girls with Rett syndrome. Spasticity or rigidity and scoliosis tend to progress, and “jerky,” truncal ataxia and apraxia become prominent.
- *Stage 4* (onset 10+ years) Progressive muscle wasting, scoliosis, spasticity, and rigidity frequently are displayed during this late stage. Decreasing mobility and a number of late stage second neuron abnormalities (e.g., drop foot abnormalities, remarkably plantar-flexed feet) may require the use of a wheelchair. Spinal cord dysfunction appears to act in

conjunction with extrapyramidal features to lessen mobility. Interestingly, this stage is marked by increased motor deterioration only. The individuals’ cognitive functioning remains stable, while social interaction (eye contact) and attentiveness improve. Seizure activity often becomes less problematic, allowing for a decrease in the anticonvulsant regimen for some girls.

Although persons over the age of 25 have been identified, the oldest being 76 years of age, little systematic research has been conducted with this group to provide information on the course of the disorder past adolescence. There is some evidence to suggest that the life expectancy of persons with Rett syndrome may be diminished; however, precise information is not available at this time.

Evaluation and Differential Diagnosis

The presentation of Rett syndrome differs considerably depending upon the stage and age of observation. For example, a child of 4 or 5 years of age with classical Rett syndrome can be correctly diagnosed with relative ease. Due to vague symptomology, diagnosis during infancy is frequently misinterpreted. Likewise, the late stage in adolescence displays a common, complex, picture of severe multiple disabilities with secondary contractures resembling any number of disorders and, therefore, often is misdiagnosed. The entire disease process must be recognized and considered to fully understand this condition.

The most common nonspecific diagnosis for children with Rett syndrome above age one is reported to be the early infantile autism (DSM-IV-TR – 299.00 autistic disorder). The behavioral patterns, progression, and prognosis of these two conditions, nevertheless, differ significantly. A basic distinction between the two disorders can be made on the basis of motor behavioral analysis (Olsson and Rett 1987; Percy et al. 1988). “Whereas autism represents a regression of verbal but not motor skills, Rett syndrome involves the simultaneous regression of both skills” (Percy et al. 1988, p. S67).

Stereotypic behavior associated with infantile autism is generally more complex and, unlike that in Rett syndrome, often involves the manipulation of an object with preservation of the pincer grasp. Persons with Rett syndrome demonstrate a very restricted repertoire of movements that appear monotonous in both form and speed.

Millichap (1987) has suggested that Rett syndrome might represent a variant of childhood disintegrative disorder (Heller's syndrome). Children with childhood disintegrative disorder develop their symptoms later (e.g., at least age 2 and typically age 3 or 4 years) than individuals with Rett syndrome, and normal neurological findings are reported in persons with the former disease.

Stage 2 developmental regressions often suggest neurodegenerative diseases. For example, the earliest stages of Rett syndrome are difficult to distinguish from infantile neuronal ceroid lipofuscinosis (INCL), an autosomal recessive disease especially frequent in the Finnish population. Both disorders cause a rapid regression of psychomotor development and the manifestation of hand and finger stereotypies at approximately the same age. As INCL progresses, however, myoclonus and retinal degeneration becomes apparent and differentiates the two disorders. Failure to designate retinopathy or optic atrophy as exclusionary criteria for Rett's disorder within the DSM-IV-TR may complicate the differential diagnosis of this disorder.

A report by Philippart (1993) links Rett syndrome with tuberous sclerosis, a neurocutaneous disorder. While this disorder may show initial similarities to Rett syndrome, close examination of the skin with a Wood's lamp and the presence of serial computed tomography abnormalities will distinguish this disorder. Chromosomal disorders, such as Angelman syndrome ("happy puppet syndrome") can display similar features to Rett syndrome. Children with Angelman syndrome, however, fail to display a period of normal development and subsequent rapid regression. Acute and chronic encephalitis may be distinguished by examination of the cerebrospinal fluid (CSF) and by a characteristic electroencephalography. The loss of language and the development of

seizures in preschool-aged children are similar in both Rett syndrome and the Landau-Kleffner syndrome. Head circumference growth and motor skills are preserved in the Landau-Kleffner syndrome.

In summary, the clinical identification of Rett syndrome rests on the careful exploration of clinical manifestations and the specific pattern of symptom progression. The differential diagnosis based upon clinical observation, while frequently difficult at presentation (especially during the earliest stages), becomes much easier after follow-up over several months to a few years. A diagnosis of Rett syndrome should involve a molecular genetic analysis to identify mutations in the *MECP2* gene.

Treatment

To date, there is no cure for the Rett syndrome, and therapeutic interventions directed at the fundamental mechanisms underlying Rett syndrome have failed to demonstrate any lasting or substantive improvements. At this time, we must be satisfied to provide suitable intervention aimed at symptomatic relief.

Seizure activity is reported in approximately 80% of persons with Rett syndrome. Selection of a specific medication should be based upon clinical seizure type and EEG pattern. Several clinicians (Budden 1986; Naidu et al. 1986) agree that standard dosages of Tegretol (C-carbamazepine) constitute the best seizure management program.

Communication abilities and subsequent programming for persons with Rett syndrome have been the topic of very limited empirical research. Prior to regression, most of the girls with this disorder are reported to have developed single spoken words and/or word combinations. Comprehension skills appropriate to the child's age also are typically noted (Budden et al. 1990; Woodyatt and Ozanne 1992). The loss of language skills during regression is sufficiently rapid to be mistaken for hearing loss. Following the regression phase of the disorder, speech and language skills are observed to be severely impaired. Verbalizations are typically nonexistent or limited to "nonfunctional" consonant-vowel

combinations, except in the estimated 2–4% of girls who fall within the preserved speech variant of Rett syndrome (Budden et al. 1990). Formal testing suggests that girls with Rett syndrome function at a pre-symbolic language level (Woodyatt and Ozanne 1992, 1993). Vocalizations, facial expressions, gestures, walking toward a desired item or activity, and eye gaze are common communicative behaviors displayed by persons with Rett syndrome.

Persons with Rett syndrome exhibit multiple orthopedic and motor movement disorders. The exact nature of these disorders can vary significantly across the different phases of the syndrome. Intensive therapy, while failing to alter the actual course of the disease, has been successful in addressing symptoms by maintaining or improving functional movement, mobility, preventing deformities, and keeping the girls in contingent contact with their environments. Therapeutic intervention is especially important, and should be more frequent, during the periods of regression associated with the disorder as transition skills are at risk.

Apraxia and *Ataxia* are frequently the earliest manifestations of motor problems in Rett syndrome. A number of therapeutic interventions have been found to be successful in the treatment of apraxia-ataxia. Tone reduction techniques similar to those used with patients afflicted with cerebral palsy or impaired through a stroke are appropriate. Interventions might include (1) use of the therapy ball, (2) balance stimulating floor activities, (3) segmental rolling, and (4) rotation and weight shift activities (Hanks 1990).

Stereotyped hand movements represent one of the most distinguishing characteristics of the Rett syndrome. Hand-wringing, hand-washing, hand tapping, and hand-to-mouth movements are common stereotypies resulting in the loss of purposeful hand function. Most researchers consider the stereotypic hand movements to represent primary circular reactions resulting from an underlying extrapyramidal disorder. Thus, they represent nonvolitional movements. Persons with Rett syndrome appear to require a great deal of concentration and effort to “break out” of the stereotypic movements even for brief attempts at purposeful

hand use. The suspected neurophysiological etiology of stereotypy in Rett syndrome has led researchers to caution practitioners attempting to modify these behaviors. As these behaviors appear to represent basically involuntary movements, attempts to change this behavior, especially through the use of aversive consequences, appear ill advised (Hanks 1990). Splinting has been found to be successful in interrupting hand-to-mouth and hand-wringing movements, thus allowing the girls to direct their attention to tasks and persons in their environment and to reduce the risk of skin breakdown related to these high-rate behaviors.

Ambulation remains one of the critical skills to develop and maintain in persons with Rett syndrome. Many of the girls fail to develop this skill prior to stage II, while others lose this ability as part of the rapid motor degeneration. As spasticity and apraxia increase, the girls often lose many of their functional gross motor skills they had previously achieved. Additionally, these girls often manifest spatial disorientation. Their perception of an upright posture results in a forward, backward, or lateral leaning. Ambulation may be lost, especially for girls with a backward lean orientation, as they are unable to initiate their forward weight shift. They fear falling when attempting weight shift in a forward direction. The abnormal gait pattern typically displayed in this syndrome results from a combination of spasticity, ataxia, apraxia, compensatory spinal rigidity, and spatial disorientation. Asymmetries may develop as one leg becomes stiffer or weaker. Weight shift is accomplished through lateral rocking, and trunk rotation is lost. More simply, because the center of balance is off, girls often think they are falling forward when they are standing normally. They try to compensate by leaning back, fall over, and over time may lose the ability to stand (Kerr et al. 1990).

Independent standing and ambulation represent a realistic therapy goal, especially in the early years. Many girls while unable to walk independently can do so with assistance. Such aided ambulation should be encouraged. Weight-bearing exercises, walking, and gait training have been successful (Hanks 1990). If

appropriate, activities designed to elicit righting and equilibrium responses might include use of the large therapy ball (prone positioning and then standing, leaning forward), weight shifting (seating the child on bench and then tipping the bench slightly backward), and ultimately active shift forward to come from sitting to standing.

Scoliosis (a side-to-side curvature of the spine) in individuals with Rett syndrome is well and kyphosis (“hunchback”) is not uncommon. Together, these deformities represent the primary musculoskeletal concern in Rett syndrome. Unfortunately, there are no rigid guidelines to predict deformity or to recommend treatment. Standard criteria (e.g., sex of patient, curve pattern, onset of menarche, Risser sign) typically useful in the determination of an appropriate intervention strategy do not appear to be of use with this syndrome (Hennessy and Haas 1988).

Reversal Learning

Karen M. Lionello-DeNolf
Psychology Department, Assumption College,
Worcester, MA, USA

Definition

Reversal learning refers to the ability to alter one's response after encountering just a few examples of a change in consequences for a behavior. Typically, reversal learning is assessed after training on simple discrimination tasks in which an individual is presented with two (or more) stimuli (such as pictures or objects), and responses to one stimulus are reinforced (i.e., followed by praise, snack foods, or access to a toy) whereas responses to the other stimulus are not. Once a learning criterion is met, the stimulus functions are reversed such that responses to the originally positive stimulus are no longer reinforced and

responses to the previously negative stimulus are reinforced. Reversals are often embedded in a variety of instructional tasks and are used as one measure of cognitive inflexibility in individuals diagnosed with a neurodevelopmental disability. Discrimination reversal procedures are also widely used in examining the neural mechanisms of behavioral flexibility.

Historical Background

There is a rich literature on the acquisition of discrimination reversals in humans from the 1950s through the 1970s, and much of this literature evolved in two different areas of psychology. In the developmental literature, researchers were interested in whether typically developing children showed developmental differences on different types of discrimination shift tasks. This work was paralleled by the work of other researchers who were interested in whether individuals with intellectual disabilities would acquire learning set (presenting new discriminations until the participant learns each discrimination in one trial), and whether they would acquire a variety of discrimination shifts, with a particular interest in reversal shifts. Both of these literatures advanced different theories for discrimination shift behavior, and they have laid the foundation for modern investigations of reversal acquisition by individuals with autism spectrum disorder (ASD). Below, these literatures will be briefly summarized.

Discrimination Shifts in Typically Developing Children and Adults

Much of the work in typically developing populations has been reviewed by Stevenson (1972), who points out that a major interest was to determine if there were developmental differences in discrimination-shift ability related to language acquisition. This area of research was heavily influenced by the work of Kendler and Kendler (1959) and their subsequent studies. There is mixed evidence for the idea that there are developmental differences regarding the ability to perform reversal shifts. Initially, groups of older children or adults were compared to groups

of younger children on two types of transfer tasks: reversal and nonreversal. The original discrimination was between stimuli that differed along two dimensions, such as color and size, and the problem could be solved by responding on the basis of a dimensional cue (e.g., objects of a particular color were always positive regardless of size). For participants given a reversal transfer task, the same dimension as in the original problem was still relevant, but the valences of the stimuli were reversed (e.g., the choices of the previously positive color were no longer reinforced and choices of the previously negative stimulus were). By contrast, for the nonreversal procedure, the relevant stimulus dimension changed (e.g., the positive stimulus was no longer defined by color, but by size). Some studies reported that older children and adults were more likely to acquire the reversal task quickly compared to the nonreversal, but other studies found no difference in the rate of acquiring the different shift tasks. Some studies investigated the role of verbal mediation on shift tasks by instructing some participants to verbalize the basis of their response and comparing them to participants who were not instructed to verbalize. On balance, these studies did not support the role of verbal mediation: the performance of groups instructed to verbalize did not differ from those not given such instructions and sometimes children would verbalize the correct response but simultaneously respond to the incorrect stimulus. Finally, giving participants overtraining on the original discrimination tended to facilitate acquisition of a reversal when visual stimuli were used but not when spatial stimuli were used. Moreover, it was found that a participant's dimensional preference exerted a strong influence on the rate of acquisition of a reversal.

Discrimination Shifts in Individuals with Intellectual Disabilities (ID)

The behavior of individuals with severe intellectual disability has long been described as rigid, perseverative, and inflexible and tests of discrimination reversals were thought to be an index of such rigidity. The reported studies tend to be group designs in which the comparison group was typically developing children matched on

mental age equivalent or IQ or a group of individuals with ID also matched on mental age equivalent or IQ. In comparison to typically developing peers, individuals with ID were reported to show deficits on discrimination reversal tasks in some studies, but not in others. Zeaman and House reported a substantial amount of work on the discrimination abilities of individuals with ID (e.g., Zeaman and House 1979). In these studies, acquisition of different types of discrimination-shift tasks were compared after learning an original discrimination to criterion. The individuals in these studies ranged in functioning level from moderate to profound disability, but specific diagnoses were rarely reported. Collectively, the results of this body of research indicated that these individuals were capable of acquiring discrimination reversal set (quicker acquisition of repeated reversal problems) of a spatial discrimination, that requiring differential responses to the two stimuli resulted in quicker acquisition of a reversal, and that prior training on a learning set task facilitated reversal acquisition. A novel finding from this literature, that contradicted the then-dominant learning theories of Hull and Spence, was the overtraining reversal effect – that providing overtraining on the original task facilitated subsequent reversal learning.

Current Knowledge

Relevance of Reversal Learning

In recent years, there has been a renewed interest in discrimination reversal learning in intellectual disabilities in general, and in autism specifically, for several reasons. First, discrimination reversals are a type of set-shifting, or the ability to alter behavior as a result of changes in the environment or context in which the behavior occurs. (Other examples of discrimination set-shifting include intra- and extradimensional shifts.) Set-shifting abilities in autism are of interest because they are part of a class of behaviors that are described as executive functioning abilities. Executive function is defined as a set of higher-order cognitive skills that require processing and integration of information from a range of both internal and

external sources. Other examples of executive functioning include planning, working memory, and inhibitory control. Some researchers have suggested that deficits in executive function may underlie the social and cognitive impairments frequently observed in individuals diagnosed with an ASD, but this does not appear to be a core deficit in the disorder. In addition, one of the three factors leading to an autism diagnosis is an excess of restricted, repetitive behaviors or interests, which may reflect deficits in inhibitory control. Performance on discrimination reversal shifts can be used to index deficits in inhibitory control because individuals are required to withhold (or inhibit) responses to stimuli when there is a history of responding to those stimuli being reinforced. Cognitive inflexibility is measured as the number of perseverative errors (i.e., repeated errors prior to switching one's selection) and regressive errors (i.e., a failure to maintain a switched response) during a reversal (Miller et al. 2015). Some researchers have suggested that an autism diagnosis may distinguishable from other diagnoses (such as attention-deficit hyperactivity disorder [ADHD] or Down syndrome) on the pattern on results across a variety of executive functioning tests, including set-shifting (e.g., Chantiluke et al. 2015). Moreover, there are reported positive correlations between set-shifting deficits and measures of repetitive and restricted interests (Yerys et al. 2009).

Performance by individuals with autism and/or intellectual disabilities on discrimination reversals is also of interest because rapid reversal responding is a prerequisite behavior for conditional discrimination tasks such as matching-to-sample (MTS) and for other tasks that tap relational learning (Dube and Serna 1998). Special education classrooms often use MTS procedures to teach students the relation between items (e.g., to teach the relation between a printed word and an object) as well as some communication skills. In addition, MTS procedures are used in standardized assessments (e.g., the Peabody Picture Vocabulary Test [Dunn and Dunn 2007] and Wechsler Intelligence Scale for Children [Wechsler 1991]). In MTS, a stimulus, the sample, is presented and after an observing period, two or

more additional stimuli, the comparisons, are presented. The individual is required to choose the comparison that goes with, or matches, the sample. Across teaching trials, the sample stimulus changes, but the same comparison options are presented. For example, on some trials, the sample may be the printed word CAT and on others it may be the printed word DOG, and the comparisons may be photographs of a cat and dog. Responses to the photo of the cat are reinforced when the printed word CAT is the sample, and responses to the photo of the dog are reinforced when the printed word DOG is the sample. In order to successfully solve this task, an individual is required to make rapid reversals across trials presented in a teaching session – whether a response to a given comparison stimulus will be reinforced changes multiple times depending on what sample is presented. Individuals with intellectual disability often have difficulty acquiring MTS discriminations, even when errorless teaching procedures are used, and the requirement for rapid, within-session reversals may be one contributing factor.

Reversal Learning Assessment

Matched comparisons. As a result of the differing contexts in which reversal learning is studied, there are several different methods that have been used to assess reversal shifts in individuals with autism and/or intellectual disability. One method has been the intradimensional/extradimensional (ID/ED) shift test from the Cambridge Neuropsychological Test Automated Battery (CANTAB; Cambridge Cognition 1996). The ID/ED shift test is presented on a computer and includes a series of nine stages in which discrimination problems of increasing difficulty are presented; four of the nine stages involve stimulus function reversals, whereas other stages involve other types of set-shifting. The dependent variables measured in this task include the number of errors to criterion per stage, the number of perseverative errors per stage, and the stage completed. Frequently, performance on this task by individuals with autism who do not have intellectual disability is compared to one or more matched comparison groups. Often, performance on the reversal stages of the task is not reported, but some studies have

included analysis from reversal stages; the data from these stages are mixed in that some studies have reported that individuals with autism make more errors on extradimensional reversals than do matched the comparison groups, whereas other studies have found no between-group differences.

Reversal shifts have also been assessed using a spatial discrimination task. In this task, an object, such as a toy, is hidden beneath one of two cups that are placed side-by-side on a table in front of the participant. On each trial, the object is hidden in the same location (e.g., always beneath the left cup). For reversal trials, the object is then switched to the alternative location without a clue to the participant. There have been mixed findings from this task; some studies have reported that children with autism make more preservative errors than comparison groups, whereas others have not found significant group differences. One contributing factor to this difference may be chronological age, as the participants in the studies that have not found deficits were younger than those in the studies that did report deficits.

Leung and Zakzanis (2014) conducted a meta-analysis of effect sizes of 72 studies investigating executive function in individuals with ASD that used a range of tests, many of which included discrimination reversals. In general, the only measure that exceeded their clinical marker threshold was an indirect measure (a behavior rating scale that was based on an informant response form assessing executive functioning in the home environment). One important difference between the rating scale and the more common direct measures (i.e., the variety of tasks that assess reversal learning) is that the former is able to capture the complexity of the natural environment in a way that the latter cannot. For example, reversal assessments conducted in a laboratory setting on a computer involve a level of instructional control that is not present when rapid reversal responding is required in the natural environment (e.g., during a conversation).

As noted above, when discrimination reversal learning is assessed in individuals with autism and no intellectual disability, there is mixed evidence for deficits relative to typically developing individuals. Recently, a few studies have been

reported in which discrimination training and reversal testing has been conducted under conditions in which not every correct response was reinforced (i.e., intermittent or probabilistic reinforcement conditions). Use of intermittent reinforcement in reversal tasks increases the overall complexity of both acquisition, initial reversal responding, and maintenance of reversal responding, which may render the task less susceptible to ceiling effects (D'Cruz et al. 2016). Because only a few studies have used this measure, it remains unclear as to whether individuals with ASD show consistent deficits; however, there are reports of deficits on intermittent reinforcement reversal tasks being linked to clinical measures of restricted and repetitive behavior.

Small-n designs. The ability of individuals with moderate to severe intellectual disability and/or autism to make rapid reversals has also been assessed in studies that did not include matched-group comparisons. In these studies, the focus was to teach behaviors that are prerequisite to MTS performance. Some studies involved within-session reversals of stimulus discriminations presented on a computer touchscreen and others studies involved between-session reversals of three-dimensional object stimuli. Despite the differences in procedures across the various studies, similar results have been found: a small number of individuals eventually are eventually able to make rapid reversals to the point of demonstrating reversal learning-set (i.e., faster acquisition of each successive reversal problem), whereas most are not (e.g., Lionello-DeNolf et al. 2008). Further, failures to observe reversal learning occurred even when errorless teaching procedures were used to teach both the original discrimination problem and its reversal. These studies can be contrasted with recent work with typically developing preschoolers (Postalli et al. 2015) and toddlers (de Sousa et al. 2015), the majority of whom acquired rapid reversal learning performances.

Finally, the acquisition of multiple reversals in the context of yoked-reversals in individuals with autism and intellectual disability is of interest because it may lead to the formation of functional equivalence (Sidman et al. 1989), one measure of

symbolic functioning. In a yoked-discrimination-reversal task, individuals are required to concurrently solve two or more simple simultaneous discriminations. Different pairs of stimuli appear on irregularly alternating trials (e.g., A1 and A2, B1 and B2, C1 and C2). Initially, one member of each pair is designated as positive (A1, B1, C1), and the other negative (A2, B2, C2). In reversal sessions, reinforcement contingencies are reversed for all stimulus pairs, and multiple yoked-reversals are conducted across sessions. On the first trial of a reversal session, individuals typically make an error (e.g., select stimulus A1 although now A2 is now the positive stimulus). Functional equivalence is indicated if, after experiencing an error with one stimulus set, the individual immediately selects the now positive (formerly negative) stimulus from all remaining stimulus pairs (e.g., B2, C2). While the number of studies reporting functional equivalence in individuals with autism and/or intellectual disabilities is small, the general pattern of results is similar to that of studies involving reversals of a single discrimination: a small number of individuals have developed functional equivalence (e.g., Santos et al. 2017), but most have not (e.g., Lionello-DeNolf et al. 2008).

Neurobiological Correlates

The neural correlates of reversal learning have been investigated in both typically developing individuals and individuals with neurodevelopmental disabilities, including ASD and ADHD. In these investigations, participants are asked to complete one or more tasks assessing reversal learning while inside an fMRI scanner, and activation of different neural systems is measured before, during, and/or after the task(s). For typically developing individuals during reversal tasks, brain regions associated with reward processing and acquisition of stimulus-response associations have been implicated (see Izquierdo et al. 2017, for a review). There tends to be increased activity in the medial orbitofrontal cortex (OFC), medial prefrontal cortex (mPFC), anterior cingulate cortex (ACC), ventral striatal regions, and the precuneus, but understanding of the roles of these (and other) areas is continuing to

evolve. The OFC may be related to the amount of discrimination training that has occurred prior to experiencing reversals and in learning about the value of trial outcomes, the ACC may be related to error detection, and the mPFC may be activated in situations that demand increased levels of attention (e.g., difficult discriminations or tracking multiple contingency reversals simultaneously).

A few studies have directly compared brain activation in (primarily male) individuals with ASD and matched controls. Reduced activation in a variety of brain areas related to decision-making and response planning in individuals with autism has been noted, including the ventral striatum, ACC, thalamus, premotor cortex, precuneus, dorsolateral prefrontal cortex, and the basal ganglia. There have also been noted increases in activation to the inferior frontal cortex and the parietal lobe (Chantiluke et al. 2015). Interestingly, individuals with autism may not differ from matched controls on behavioral measures of reversal learning even though the two groups may show different patterns of brain activation.

Finally, investigations of the neurochemical correlates of reversal learning have been conducted in nonhuman animals. These studies indicated that reduced levels of serotonin in the cortex is associated with increases in perseverative errors, and reduced levels of dopamine in the striatum is associated with increases in non-perseverative errors. The role of glutamate has also been investigated, but the data are conflicting. For all three neurotransmitters, there is some evidence that effects may be modulated by particular receptor subtypes.

Future Directions

Given the marked variability across investigations of reversal learning, more study is warranted in order to make more definitive statements about the capability of individuals with autism and/or intellectual disability on these tasks sorts of tasks. There are several variables that may contribute to the observed variability across studies, including the age of the

participants, the severity of intellectual disability, the level of verbal ability, task demands unrelated to reversals (e.g., higher-order cognitive skills), and the severity of symptoms in the domain of restricted, repetitive behavior. In particular, more studies that include younger individuals, female participants, and individuals with intellectual disability are needed. Given the ubiquity of stimulus reversals in teaching procedures and standardized assessments and the importance of stimulus reversals for communication and other forms of symbolic functioning, research is needed to determine which variables are critical for rapid reversal performance and the maintenance of that performance. Moreover, given the relative paucity of work investigating neural correlates of reversal learning in ASD, particularly in children and individuals with ID, additional work should be conducted. Finally, there have been a few reports of reversal learning in Pavlovian fear conditioning tasks (South et al. 2012), and performance has been correlated with restricted and repetitive behavior but not anxiety. Additional work in this area is needed before firm conclusions can be made. Collectively, work in these different areas could lead to interventions that encourage reversal learning and perhaps increase cognitive flexibility and symbolic communication in individuals with ASD.

Revised Knox Preschool Play Scale (RKPPS)

Zachary Warren¹ and Elizabeth Howell Dohrmann^{2,3}

¹Vanderbilt Kennedy Center, Treatment and Research Institute for Autism Spectrum Disorders (TRIAD), Nashville, TN, USA

²Treatment and Research Institute for Autism Spectrum Disorders (TRIAD), Nashville, TN, USA

³Department of Psychiatry and Biobehavioral Sciences, Child and Adolescent Psychiatry Fellowship Program, Semel Institute for Neuroscience and Human Behavior, Resnick Neuropsychiatric Hospital, UCLA David Geffen School of Medicine, Los Angeles, CA, USA

administered in environments familiar to the child. The scale includes two 30-min observations of the child in different settings, one indoor and one outdoor. The test developer, S. Knox, has also indicated that two 15-min sessions may also be acceptable (see Jankovich et al. 2008). The scale consists of 4 dimensions and 12 categories of play behaviors, from which the therapist develops a “play profile.” This information is useful for assessing potential disabilities and planning appropriate interventions.

The four dimensions included in the RKPPS are the following: (1) space management, (2) material management, (3) pretense/symbolic, and (4) participation. Within these dimensions exist the 12 categories of play behaviors, also referred to as “factors.” Under “space management” exist the (1) gross motor and (2) interest factors. Within “material management” exist the factors of (3) manipulation, (4) construction, (5) purpose, and (6) attention. Under “pretense/symbolic” are the factors of (7) imitation and (8) dramatization and under “participation,” (9) type, (10) cooperation, (11) humor, and (12) language.

The RKPPS is scored in terms of ages: the 4 dimension ages and 12 category ages yield an overall play age. The developmental age estimates are divided into 6-month increments between the ages of 0 and 36 months (e.g., an estimate for a dimension age could be 6–12 months) and 12-month increments between the ages of 36–72 months (e.g., 48–60 months). Children are scored only according to demonstrated skills and not skills that are emerging, as per supplemental instructions from the authors.

[PPS](#)

Description

The RKPPS is a standardized instrument designed to evaluate play in children and correlate it to an approximate developmental age. It can be used to assess children aged birth to 72 months and is

Historical Background

Assessing play is simultaneously a complex and important task for service providers attempting to appropriately understand child-specific developmental vulnerabilities and skills in a manner that can be utilized to quantify current functioning and guide intervention services and techniques. Historically, practitioners in the field of occupational therapy have used a number of play assessments (e.g., Parten Social Play Hierarchy (Parten

1932), Play History (Takata 1969)) that examine certain components of play (i.e., imitation, creativity, rule organization) but do not yield results in terms of an overall developmental outcome or age. The Preschool Play Scale (Bledsoe and Shepherd 1982) was designed to examine play in a standardized manner and provide specific developmental markers of import. In 1997, this scale was revised by Knox to the current version, the Revised Knox Preschool Play Scale (RKPPS) (Knox 1997). Knox had, in 1974, developed “A Play Scale” (Knox 1974, 2005) to assist in determining developmental play ages, and this measure had several advantages: it assessed children in their natural environments and therefore catered to children who have difficulty conforming to standardized measures, all while delivering a developmental approximation. Knox’s revisions to the Preschool Play Scale included changes to the scoring scale and descriptor clarity. However, despite these modifications, the unrevised Preschool Play Scale continues to be used more frequently than the RKPPS due to a lack of reliability and validity data on the latter.

Psychometric Data

Extensive psychometric data regarding the use of this instrument within diverse samples of individuals with autism and other developmental disorders is not available. Recent interrater reliability analyses from Jankovitch et al. (2008) showed an 87% agreement between raters for the overall play age on the RKPPS when the scored ages were within 8 months of each other. In the same analysis, the interrater agreement rates for the play ages within fewer than 6 months of each other in the four domains ranged from 63.2% to 81.6%. Rates reached 91.7–100% agreement for the four domains when the age range expanded to a 12-month difference. When separated into age levels, the two raters agreed within the same range 81.8–100% of the time on all 12 RKPPS categories. In terms of construct validity, Jankovich et al. (2008) also addressed the RKPPS’s ability to measure the theoretical construct of “play.” By examining the scores of typically developing

children and comparing their chronological ages with the calculated play ages, they concluded that the construct validity of RKPPS was supported. They noted, however, that the older age groups were more accurate in the matches than the younger, 36–47-month age group, where 6 of the 14 children had play scores higher than their actual chronological ages.

Clinical Uses

The RKPPS is used clinically in the assessment of play in children ages 0–72 months in order to determine a developmental play age, screen for possible developmental concerns, and develop intervention programming. The measure is administered by trained examiners, generally occupational therapists. The recent reliability data suggest that scores up to 8 months below or above the child’s actual chronological age indicate that, without other factors or concerns, the child’s performance should be considered within typical ranges. The RKPPS has not yet been validated in a sample of children with a range of developmental disabilities or from varying socioeconomic, geographical, and cultural groups, although steps have recently been taken in that direction, notably in Brazil, where a Portuguese adaptation of RKPPS was preliminarily tested (see Pacciulio et al. 2010). Additionally, the RKPPS has been used in assessing differences in play between children with and without developmental coordination disorder (Kennedy-Behr et al. 2013).

Key Auditory Verbal Learning Test (Rey AVLT)

Dermot Bowler

Autism Research Group, City University London,
London, UK

Synonyms

Auditory verbal learning test; AVLT; RAVLT

Description

The Rey Auditory Verbal Learning Test (RAVLT) provides a standardized procedure to

evaluate a range of aspects of verbal learning and memory of supra-span lists of words. The test requires recalling as many words as possible in any order from a standard list of 15 unrelated words read out by the examiner. This procedure is repeated for four further trials, the words being presented in the same order on each trial. The words all have either one or two syllables, are high in imagery, and have a Thorndike-Lorge frequency of at least 50 per million. On each trial, the examiner records the words recalled, including repetitions and intrusions of words not present in the study list. Different authors have used a variety of procedures following Trial 5. In Rey's (1941) original version of the test, a short story containing the 15 studied words was presented, with a request to identify the studied words in the story. However, more recent versions of the test (e.g., Lezak et al. 2004) omit this step and proceed directly to the presentation and testing of a second list of words (Trial 6) followed in Trial 7 by a request to recall the original list. Many researchers also test delayed recall of the original list 20 min after the initial five learning trials (Trial 8) immediately followed by a 50-word recognition trial (Trial 9). Some authors (e.g., Vakil and Blachstein 1997) have added an additional trial in which the 15 words of the first-presented list were presented, written in a different order from that in which they were first presented. The task was to reorder the words according to the original sequence. A set of alternative word lists are available for use as parallel versions of the original list used in Trials 1–5, as well as of the second-learned list and the story or word list used to test recognition. These parallel forms permit repeated testing in order to measure changes in memory performance over time and can be found in Schmidt (1996). On all trials, the examiner keeps a detailed record of the words recalled or recognized, including repetitions, new words, and intrusions from earlier-learned lists.

The instructions for administering the test vary somewhat in different versions and experimental investigations, but all versions make explicit that the test is one of memory and learning and that the aim is the accurate recall (or recognition, where

appropriate) of as many as possible of the presented words in any order.

A wide range of measures can be obtained from the RAVLT. Norms are available for many of these, but the raw data can also be utilized to compare different groups of participants or to evaluate performance over time or in response to particular interventions. The following sections list the most widely used measures in the literature. The terms T1 through T9 refer to the total number of correct items in the nine testing trials described above.

A large number of *derived measures* can be obtained from the data obtained on the nine individual trials. *Learning rate* (T5–T1) provides an overall measure of how much additional material is retained on the four trials following the initial presentation. This measure can be further broken down by considering performance on the *learning curve*, which looks at the patterning of performance on each of the trials T1, T2, T3, T4, and T5. Summing the numbers of correct items across these five trials yields a measure of *total learning*. In order to control for the effect of initial memory performance on this measure, Ivnik et al. (1990) advocate correcting this measure by subtracting from it five times the score on T1 thereby yielding a *corrected total learning* score. An index of *best learning* is provided by the score on T5, and a *learning rate ratio* is obtained by dividing T1 by T5. An index of *delayed recall* is provided by the score on T8.

As well as measures of learning and recall, indices of underlying learning processes can also be obtained. Difference and ratio measures of *proactive interference* can be calculated by respectively subtracting T6 from T1 or by dividing T6 by T1. Similarly, difference and ratio measures of *retroactive interference* can be obtained by subtracting T7 from T5 and dividing T7 by T5, respectively. Difference and ratio measures of *forgetting rate* can also be obtained by subtracting T8 from T5 or by dividing T8 by T5. A measure of *freedom from distraction* is obtained by subtracting T6 from T5.

Further information on the dynamics of learning and memory in the test can be obtained from a

consideration of *additions*, which is the sum of new words in Trial N that are not recalled in Trial N-1, and *omissions*, which is the sum of words not recalled in Trial N that were recalled in Trial N-1. *Intrusions* – non-studied words that appear in recalled lists and *repetitions*, words that are repeated in the same recall trial – can also be recorded.

If a recognition memory trial (T9) is included, a simple measure of *recognition* is obtained by subtracting false alarms (FA, the number of non-studied words indicated as having been studied) from the number of hits (correctly recognized study words). Vakil and Blachstein (1997) have also suggested using a *nonparametric signal detection measure of recognition* using the formula $[5 (1 + \text{Hits} - \text{FA})]$. These authors also suggest computing difference and ratio versions of *retrieval efficiency* by subtracting T8 from T9 or dividing T8 by T9, respectively.

Researchers have also derived a number of other measures to evaluate the dynamics and organization of learning over the test. For example, Lezak (1983) suggests that Trial 1 performance usually matches an independently measured digit span score and that differences between the two may give clues to attentional, motivational, or emotional difficulties. The shape of the learning curve can indicate learning difficulties, especially when associated with a poor delayed recall score (Bishop et al. 1990). Altered serial position effects are also seen. Typical, healthy individuals recall more of the first and last items of a list and fewer of the middle items. These *primacy* and *recency* effects are maintained over trials for healthy individuals but are attenuated in individuals with lesions of the frontal lobes (Eslinger and Grattan 1994).

Some researchers have also investigated the *subjective organization* – the extent to which an individual reorganizes order of the items in a way that differs from the presented order – of recall across trials of the RAVLT. Diminished subjective organization has been reported in learning-disabled children (O'Donnell et al. 1988), children with specific language impairment (Records et al. 1995), and patients with frontal lobe damage

(Eslinger and Grattan 1994) but not in high-functioning adults with ASD (Bowler et al. 2009).

A potential limitation of the RAVLT in comparison with other verbal learning tests such as the California Verbal Learning Test (Delis et al. 2000) is that the studied words are not strongly semantically related. Although this results in the various measures described above being relatively uncontaminated by semantic organization, it does not permit measurement of semantic clustering. Tests, such as the CVLT, which contain lists made up of words from more than one category or different categories enable the extent to which semantically related material can be clustered in recall.

Historical Background

The evaluation of memory difficulties forms a major part of the work of clinicians involved in the assessment of individuals with brain damage, psychiatric or neuropsychiatric syndromes, or with developmental disorders. It was in this context that the Swiss psychologist, Édouard Claparède, first formalized a test involving the recall of 15 unrelated words, together with a procedure for administration of the test (Claparède 1919, see Boake 2000). As Boake points out, this makes the auditory verbal learning test one of the oldest mental measurements in continuous use. Another Swiss psychologist, André Rey, further developed the standardization of this test, which now bears his name. Rey's intention was to evaluate his neurological patients' memory performance in relation to the range of values that would typically be expected for similar individuals selected on the basis of parameters such as gender, age, educational level, socioeconomic status, ethnicity, etc. Since the development of Rey's original version of the test, it has been translated into several languages including English.

Psychometric Data

A wide range of norms are available for use with the RAVLT, which are comprehensively reviewed

in Schmidt (1996), as well as in Mitrushina et al. (1999) and Spreen and Strauss (1998). Schmidt is at pains to point out that different sets of norms have often utilized slightly different word lists and procedures. This means that care needs to be taken to ensure that the word lists and procedures used match those of the chosen normative data. It is also important to be aware that normative data are not always available for all possible measures that can be derived from the test. Schmidt (1996) also provides a set of metanorms obtained by pooling the data from methodologically sound normative studies published up to that date. In addition to the original French language norms published by Rey (1958), norms have also been published in other languages including Dutch (Van der Elst et al. 2005), Greek (Messinis et al. 2007), and Hebrew (Vakil et al. 2010). Several studies have also published data on age-related changes in RAVLT performance in both children and adults. In addition to those reviewed in Schmidt (1996) are those on Dutch children by van den Burg and Kingma (1999), on older English-speaking adults (Steinberg et al. 2005) and on Hebrew-speaking older adults (Vakil and Blachstein 1997).

Test-retest reliability has been assessed by a number of studies, and the existence of parallel forms of the test permits estimations that are relatively uncontaminated by practice effects. Schmidt (1996) reviews these studies and concludes that performance is more stable on later than on earlier trials and that reliability is higher for the recall than for the recognition trials. Good reliability is also reported for measures that are derived from performance on individual trials.

Given that it tests multi-trial recall of verbal material, the *face* and *content validity* of the RAVLT are undoubtedly high. Its *concurrent validity* as measured by how well it correlates with performance on other tests of memory is also high. Schmidt's (1996) review of validity studies concludes that factor analytic studies of memory that have included the RAVLT have generally shown that it loads with other measures of verbal memory as well as with measures of general verbal ability but not with measures of motor or visuospatial ability.

Several investigators have investigated the *factor structure* of the test, with different investigators identifying different numbers of factors, which in turn correlate with different subsets of the test items. Talley (1986) reports two factors (short-term memory and long-term memory), whereas Vakil and Blachstein (1993), using Hebrew-speaking participants, report three (acquisition, storage, and retrieval). More recently, Baños et al. (2005) reported three correlated factors (general verbal learning, auditory attention, and inaccurate recall) in a group of adults with spinal cord injury.

Clinical Uses

As befits a test whose origins lie in the area of clinical evaluation, the RAVLT has been utilized with a wide range of clinical conditions. These include memory impairments that result either from neurodegenerative disease, brain injury, or developmental disability. It has also been utilized to evaluate cognitive changes in healthy aging as well as at different stages of diseases, such as HIV infection, which are known to produce cognitive impairments. These studies are reviewed by Schmidt (1996) as well as by Lezak et al. (2004) and by Strauss et al. (2006). To date, only one study has used the test with individuals on the autism spectrum. Bowler et al. (2009) found no overall deficit in recall or learning in a group of high-functioning adults with autism spectrum disorder (ASD). Although these participants were found to have typical serial positions on Trial 1, by Trial 5 their primacy effect was found to lag significantly behind that of a typically developed comparison group. The authors speculate that this patterning of serial position effects over trials may result from a more item-specific strategy driven by greater attention to the perceptual rather than the conceptual aspects of the studied words.

Reynell Developmental Language Scales

Elizabeth Schoen Simmons
Department of Psychological Sciences,
University of Connecticut, Storrs, CT, USA

Synonyms

NRDLS

Description

The New Reynell Developmental Language Scales (NRDLS) is the current edition of the Reynell Developmental Language Scales. The NRDLS is a norm-referenced assessment that measures expressive and receptive language skills in children 2–7 years of age. It contains two scales – Verbal Comprehension and Production. The Verbal Comprehension Scale measures language understanding of nouns, verbs, and prepositions. It also measures a child's ability to follow simple and complex directions and provides information on comprehension of basic inferences. The Production Scale measures spoken language in the areas of syntax, vocabulary, and content.

Historical Background

The RDLS was initially created in the United Kingdom with normative data collected in Britain. The British version is in its fourth revision (NRDLS: The University of Reading Edition; Edwards et al. 2011). There is also an American version, published in 1990 (Reynell and Gruber 1990).

Psychometric Data

The American version has a normative sample of 600 children with data collected across the United States. The sample is representative of the United States ethnic composition, parental education, and geographic regions.

Clinical Uses

The test is quick to administer, taking less than 30 min to complete. The NRDLS uses both manipulatives and pictures, making it a good choice for children with developmental disabilities. It provides standard scores, percentile ranks, and age equivalents for both expressive and receptive language skills.

[Developmental right-hemisphere syndrome](#); [Non-verbal learning disabilities \(NLD\)](#); [Right-](#)

[hemisphere deficit syndrome](#); [Right-hemisphere developmental learning disability](#); [Right-hemisphere learning disability](#); [Social-emotional processing disorder](#)

Short Description or Definition

Compromised functioning of the right hemisphere is associated with impairments in attention; non-verbal memory; visual-perceptual and visual-spatial abilities; and the expression, recognition, and integration of emotion and affective states. In adults, the behavioral and neuropsychological sequelae of *acquired* injuries to the right hemisphere of the brain (e.g., through stroke, tumor, or traumatic brain injury) are well documented and described. Several researchers have also endeavored to examine and describe a similar syndrome on a developmental basis. The name of the proposed disorder has varied with each account (see above).

In these accounts, individuals with social difficulties, a characteristic neuropsychological profile, academic challenges, and neurological signs consistent with right-hemisphere damage or dysfunction have been identified. The syndrome has been described in children with documented perinatal or early childhood brain damage (e.g., Voeller 1986) as well as in children with no obvious evidence of brain damage (e.g., no structural lesions or seizure disorder) (Gross Tsur et al. 1995; Rourke 1989). Rourke (1989) isolated the syndrome, referred to as nonverbal learning disability (NLD), in his research of children with learning disabilities; Gross Tsur et al. (1995) described a specific set of impairments in children referred to a clinical center for social, behavioral, and/or academic problems. Findings have also been presented in adolescents and adults; those for whom neurodiagnostic examination suggested early brain injury affecting the right hemisphere and inadequate development of the functions it normally subserves (Manoach et al. 1995; Weintraub and Mesulam 1983) and those with no history of acquired cerebral injury or evidence of structural abnormality (Tranel et al. 1987). In the latter instance, the

neuropsychological evidence was suggestive of right-hemisphere dysfunction and the pattern of cognitive and behavioral functioning was life-long; the constellation of symptomatology was considered to represent a developmental learning disability of the right hemisphere.

In sum, this syndrome is predicated on a neurobehavioral and psychological profile seen in individuals with right-hemisphere damage, but its manifestation does not necessitate a demonstrable lesion. A developmental disorder of the right hemisphere is also proposed; that is, a pattern of results and behavioral phenotype suggestive of right-hemisphere dysfunction in children, adolescents, and or adults who have no obvious structural brain damage. Rourke's model is somewhat distinctive, both for being more fully developed and for encompassing three dimensions and progressions in neurodevelopment ("down-up," "back-front," as well as "right-left"); the principal working hypothesis of this model is that the behavioral phenotype of NLD will be manifest to the extent that white matter (long myelinated fibers) in the brain is underdeveloped, damaged, or dysfunctional (Rourke 1989, 1995).

Clinical Expression and Pathophysiology

The clinical expression of this disorder is based on case reports defining the core symptoms to include:

- Emotional difficulties (e.g., perception and interpretation of the emotional states of others, nonverbal expression of emotion, depression)
- Impaired interpersonal skills (e.g., shy, withdrawn, isolated, poor peer relationships)
- Paralinguistic communication deficits (e.g., atypical prosody, reduced eye contact, diminished or exaggerated facial expression and body gestures, literal interpretations)
- Poor visual-spatial ability often in the context of average or superior verbal abilities
- Academic deficits, especially in arithmetic with better developed reading and spelling skills
- Left-sided neurological findings

Attention deficit hyperactivity disorder is reported to be part of the clinical picture in several instances (e.g., Gross Tsur et al. 1995; Manoach et al. 1995; Voeller 1986). Graphomotor problems are generally noted; difficulties copying and drawing geometric and representational designs are consistent with right-hemisphere dysfunction. Rourke reports improvement in the handwriting of children with NLD over time, with repeated practice.

In the work on NLD, which has spanned several decades, the content and dynamics have been detailed (Rourke 1989) and classification rules derived for 9- to 15-year-old children (Pelletier et al. 2001) and 7- and 8-year-old children (Drummond et al. 2005). (Please see ► [“Nonverbal Learning Disabilities \(NLD\)”](#) entry in this Encyclopedia for more information.)

Although not identified in the case reports above, additional impairments associated with right-hemisphere damage include:

- Left-side neglect
- Difficulty identifying relevant information
- Problems with conversational rules
- Confabulation
- Disorientation in time and direction
- Anosognosia (failure to recognize the symptom's of one's own illness)
- Prosopagnosia (inability to recognize familiar faces)

Evaluation and Differential Diagnosis

Neither right-hemisphere syndrome nor any of the related syndromes listed above are recognized in the DSM-IV-TR. The terms *right-hemisphere learning disability*, *developmental learning disability of the right hemisphere*, and *social-emotional learning disabilities* (Denckla 1983; Weintraub and Mesulam 1983) emerged from the neurological field and *nonverbal learning disability* (Rourke 1989) from the field of neuropsychology. In some instances, individuals with Asperger syndrome may show a similar pattern of neuropsychological strengths and weaknesses as identified in these conditions (Klin et al. 1995).

A comprehensive neuropsychological examination is recommended, assessing cognitive, behavioral, social-emotional, academic, and adaptive functioning. The developmental history is also important, especially if the evaluation is occurring at a later developmental period (e.g., middle school or high school years).

Differential diagnoses include ADHD, mood disorders, and personality disorders. As noted above, in several of the case reports (Gross Tsur et al. 1995; Manoach et al. 1995; Voeller 1986), the clinical presentation was also significant for attention deficit disorder, with or without hyperactivity. A relationship between right-hemisphere involvement, attention deficit disorder, and depression has been hypothesized by others (e.g., Brumback and Staton 1982) and there is evidence that attentional processes are subserved by right-hemisphere pathways. Rourke (1989) offers a developmental perspective, that is, the diagnosis of ADD in children with NLD is usually based on inattentiveness to visual and tactile stimuli in the very early school years. Much of the “teaching” that takes place in the earliest school years is visually mediated and requires “hands on” exercises, tapping areas of deficit in children with NLD. The inability to complete such tasks or process such information may be misinterpreted as a primary failure in attention. From this perspective, inattention is thought to be a secondary deficit that stems from more basic deficits in primary visual and tactile perception.

Rourke and colleagues have identified the following pattern in individuals with NLD: children with NLD are characterized during early childhood as presenting with some type of acting-out or other “externalized” disorder but are at risk for the development of “internalized” forms of psychopathology, such as anxiety and depression, in adolescence and adulthood. Depression was reported in the adolescents and adults in Manoach et al.’s sample who were selected on the basis of meeting criteria for a social-emotional processing disorder (SEPD).

Grace and Malloy (1992) identified patients in an adult psychiatric population with evidence of a right-hemisphere learning disability (RHL),

seeking to examine the contribution of this disorder to adult psychiatric presentations. Many of the adults with RHL presented with depression; however, their developmental histories were distinct from other patients with clinical depression. The test performance of individuals with major depression may yield visual-spatial deficits and deficits secondary to psychomotor retardation on timed nonverbal tasks. However, for the RHL individuals with comorbid depression, the developmental history was significant for persistent problems in childhood with visual-spatial tasks, attention, social isolation, which predated onset of affective symptoms. Moreover, the pattern of neuropsychological deficits remained stable over time and did not resolve with improvement of psychiatric symptoms.

In Grace and Malloy’s psychiatric sample, episodic dyscontrol and psychotic disorders as well as several instances of psychosexual developmental issues were noted in their RHL group. Given the overlapping clinical features, these adolescents/adults may be identified with schizoid personality disorder or schizoaffective disorder; Rourke speaks to the issue of diagnostic overshadowing as concerns the diagnosis of disorders along the schizophrenia continuum in individuals with NLD (see www.nld-bprourke.ca Q&A).

Treatment

Recommendations for treatment include providing modifications to instructional materials, accommodations for areas of impairment, and support strategies for enhancing development of areas of deficiency. Comprehensive recommendations are provided by Rourke (1989, 1995) and Thompson (1997) as pertains to NLD. Some general recommendations identified for individuals with right-hemisphere syndrome include the following:

- Help the individual learn how to interpret social cues that occur in everyday interpersonal interactions.
- Provide explicit teaching of nonverbal cues (both interpretation and expression).

- Avoid sarcasm and/or metaphors when speaking to the individual.
- Provide a consistent routine.
- Make expectations explicit (no “reading between the lines”).
- Break down tasks into small steps and provide straightforward, sequential verbal descriptions.
- Repeat directions as needed.
- Decrease distractions when communicating.
- Consider that in many instances the behavior difficulties demonstrated by these children reflect situations where their processing capacities are overwhelmed or where they do not know the correct way to respond.

Riluzole

Jonathan Kopel
Texas Tech University Health Sciences Center
(TTUHSC), Lubbock, TX, USA

Synonyms

[Rilutek](#); [Teglutik](#)

Definition

Riluzole is used for amyotrophic lateral sclerosis and prevention of ventilator dependence after a tracheostomy (Wink et al. 2011). Current pharmacological studies suggest riluzole modulates glutamate-induced excitotoxicity and inhibits the release of glutamate from presynaptic nerve

terminals (Wink et al. 2011). Common side effects of riluzole include headache, gastrointestinal distress, and decreased salivation. In recent years, several clinical studies and clinical trials have investigated riluzole's therapeutic efficacy for mood disorders, such as anxiety and depression (Wink et al. 2011). Among autism spectrum disorder patients (ASD), riluzole was effective in reducing repetitive behaviors and irritability (Wink et al. 2011). However, a single case report suggests riluzole may increase the concentration of other antipsychotic, antidepressant, or anticonvulsant drugs used for ASD patients through inhibition of CYP enzymes (Veenstra-VanderWeele 2010). Furthermore, a randomized placebo-controlled cross-over consisting of seven patients suggested that Riluzole was ineffective at reducing irritability despite being well-tolerated by ASD patients (Wink et al. 2018). However, a larger randomized study of 49 ASD patients showed a significant improvement in irritability, decreased social withdrawal, stereotypic behavior, and hyperactivity (Ghaleiha et al. 2013). Overall, riluzole shows promise for improving the social and cognitive deficits of ASD patients without significant adverse events.

Rimland Diagnostic Form for Behavior-Disturbed Children (Form E-2)

Description

The Rimland Diagnostic Form for Behavior-Disturbed Children (Form E-1) was created in 1964 as a measure for identifying autism (Rimland 1964). The revised version, Form E-2, has 79 items related to the child's behavior and development since infancy and relies on retrospective information from the parents (Prior and Bence 1975). It includes characteristics such as cognitive, emotional, and perceptual development; speech development; obsessive behavior; and family background.

Historical Background

Form E-1 was the first diagnostic scale to be used to identify autism (Lord and Corsello 2005). It was created to systematically focus on a carefully selected range of symptoms rather than the inconsistently defined concepts relied upon by most measures at the time. The creation of the Rimland forms enabled clinicians to diagnose autism and

researchers to compare individuals objectively. It was originally designed to distinguish children with autism from those with schizophrenia, and the measure was revised to Form E-2 to differentiate between children with and without autism (Prior and Bence 1975; Rimland 1964). The scale was based on the current perspective on autism at the time, as described by Kanner in 1943 (Lord and Corsello 2005).

Psychometric Data

The original version of the Rimland, Form E-1, contained 76 questions to be answered by parents (1968). Rimland found that the parents' responses showed that the core symptoms of autism were more diffuse and idiosyncratic for children over 5½ years of age when compared to younger children (Morgan 1988). In response, he created the revised version, Form E-2, which addressed only children under the age of 5.

For each item on the checklist, a positive point was given for an answer that aligned with early infantile autism and a negative point for each behavior representative of a typically developing child, resulting in a total score (Morgan 1988). Rimland analyzed a sample of 2,218 completed forms and found total scores ranging from -42 to +45; the cutoff score that Rimland determined to be diagnostic of infantile autism was +20. He determined that only 10% of his sample scored +20 or higher, which was consistent with Kanner's belief that "true" autism is manifested in only 10% of children labeled as autistic (Parks 1983; Rimland 1971).

Several studies have demonstrated that the E-2 yields diagnoses that are different from those determined by most other diagnostic instruments (Lord and Corsello 2005). One example is the original validation study of the Childhood Autism Rating Scale (CARS; Schopler et al. 1980). Over 200 children who met the criteria for autism and 200 typically developing children were all rated on the E-2 form, and only 8 were considered to have autism by the E-2 form; of those 8, 3 were considered not to have autism on the CARS,

demonstrating a discrepancy between the two measures. Another study compared the E-2 to the Behavior Rating Instrument for Autistic and Atypical Children and found minimal diagnostic overlap (Cohen et al. 1978; Rutter et al. 1966). In addition, several studies have suggested that there are significant differences between parent and staff reports using the E-2 scale (Davids 1975; Prior and Bence 1975) and that the measure cannot differentiate between children with autism and children with other disorders (Lord and Corsello 2005). No interrater reliability, internal consistency, or test-retest reliability has been reported on the E-2 form (Parks 1983).

Other types of validity have been assessed for the E-2. The content validity of E-2 relies on Kanner's strict criteria for autism (1943) as well as on Rimland's (1964) review of relevant literature on the developmental and medical characteristics of children with autism (Morgan 1988). Several studies have examined the construct validity of the E-2 by comparing it to biological variables (Morgan 1988). Rimland (1971) and Boullin et al. (1971) reported that children with high levels of serotonin outflow had high E-2 scores. However, a later study (Yuwiler et al. 1975) was not able to replicate this finding. Rimland (1973) examined the relationship between E-2 scores and the response of children with autism and psychosis to megavitamin therapy. His results indicated that those children who showed a positive response to therapy had higher E-2 scores than those with no response, but this finding has not been replicated (Morgan 1988).

DeMyer, Churchill, Pontius, and Gilkey (1971) addressed discriminant validity when they found that both the E-1 and the E-2 could distinguish between psychotic (early schizophrenic and autistic children) and nonpsychotic children. Only the E-1 could discriminate between autistic and schizophrenic children.

Clinical Uses

Since the creation of the Rimland forms, the ways in which symptoms of autism are defined and

weighted have changed substantially, rendering the E-2 as an ineffective diagnostic tool (Lord and Corsello 2005). However, the E-2 forms may remain useful to parents starting to learn about behaviors to expect with autism. The E-2 form is currently scored without charge for parents by the Autism Research Institute in San Diego.

Major Appointments (Institution, Location, Dates)

- Director, Autism Research Institute, San Diego, CA

Landmark Clinical, Scientific, and Professional Contributions

A psychologist who worked for the US Navy as a researcher, Dr. Rimland's interest in autism arose when his son was diagnosed with the condition. At that time, the "refrigerator mother" notion of causation was still prominent (e.g., through the work of Bettelheim and others); Rimland conducted his own research, and in a groundbreaking book *Infantile Autism: The Syndrome and Its Implications for a Neural Theory of Behavior*, he provided a strong argument for the neurobiological cause of the condition. He also was the developer of one of the first rating scales for autism. His emphasis on the brain rather than caretaking as a cause of autism helped to focus the field and also led to a changed emphasis on teaching and intervention rather than psychotherapy for the condition. A tireless advocate for individuals with autism and their families, Rimland was quick to support the behavioral approaches developed for the condition and also was quick to rally support against facilitated communication. He had a leadership role in the Autism Society of America. He was the director of the Autism Research Institute in San Diego. In 1967, Dr. Rimland established the Autism Research Institute (ARI). This served as the base of his operation and the repository for data collected using his rating instrument. In the 1980s, after his retirement from the Navy, Dr. Rimland focused his efforts on new treatments, many of which remain controversial

(e.g., vitamin treatments, the role of vaccines in autism, and so forth). In 1985, after retiring from his day job as a Navy researcher, Dr. Rimland's research and ideas made him perhaps more prominent and took him outside the scientific mainstream. He published papers on the effects of high doses of vitamin B6 for autistic children. Tens of thousands of parents have said the vitamins helped their children, but most academic researchers have been skeptical.

Short Biography

Born in Cleveland, Ohio, Rimland relocated with his family to San Diego while he was a child. He attended San Diego State University earning a bachelor's degree in experimental psychology and a master's the following year. He completed doctoral studies at Pennsylvania State University in 1954. He then returned to work in San Diego for the US Navy as a researcher. His background in research fostered his work on the cause of autism.

Risk of ASD in Individuals with Down Syndrome

Marie Moore Channell

Department of Speech and Hearing Science,
University of Illinois at Urbana-Champaign,
Champaign, IL, USA

Synonyms

Comorbid ASD; Co-occurring ASD

Definition

Individuals with Down syndrome (DS) are at increased risk for autism spectrum disorder (ASD). Current best estimates suggest that up to 19% of individuals with DS have co-occurring, or comorbid, ASD (Glennon et al. 2017). This prevalence rate is much higher than the ~2% ASD prevalence rate in the general population.

DS is a neurogenetic disorder caused by the triplication of chromosome 21, and it is the most common genetic cause of intellectual disability. A diagnosis of intellectual disability includes delayed cognitive development (i.e., lower than average IQ) and difficulties in adaptive functioning (e.g., practical skills or self-help skills) that impact daily function (AAIDD 2010). DS is also linked to a behavioral phenotype – a syndrome-specific profile of relative strengths and weaknesses – in cognitive, linguistic, and socio-emotional skills and behaviors that impact social communication and interaction. Compared to individuals with DS alone, those with DS who also have ASD are at risk of poorer outcomes – such as more severe cognitive impairment, fewer adaptive skills, and more challenging behaviors – that impact learning and independent living opportunities. Early identification of comorbid ASD is important because it leads to earlier intervention and treatment options and more favorable long-term outcomes (Glennon et al. 2017).

DS is usually diagnosed around birth and confirmed with genetic testing. It takes longer, however, for ASD symptoms to emerge, and the ASD diagnostic process requires clinical observation and behavioral testing. According to the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5; APA 2013), a diagnosis of comorbid ASD in individuals with intellectual disability such as DS requires evidence that observed impairments in the domains of (a) social communication and interaction and (b) restricted, repetitive patterns of behavior cannot be explained by intellectual disability alone. Thus, when screening for ASD in individuals with DS, a practitioner must consider the individual's overall developmental level *and* the DS behavioral phenotype to determine whether observed impairments are typical for DS or signal comorbid ASD.

This can be a challenging task, especially because commonly used ASD screening tools were not designed for populations with intellectual disabilities. As a result, these tools may falsely identify ASD risk in individuals with DS based on behaviors that are more indicative of their intellectual disability (e.g., lack of flexibility; difficulty interpreting social cues) or the DS phenotype (Channell et al. 2015). For example, one of the most prominent features of the DS behavioral phenotype includes expressive language difficulties; these impact social communication and interaction, a domain also affected by ASD. Therefore, the practitioner must understand the symptoms that are typically associated with DS to determine if comorbid ASD is present beyond these symptoms.

On the other hand, there are certain maladaptive behaviors (e.g., inattention; social withdrawal; socially offensive behaviors) that could serve as red flags for comorbid ASD specifically in DS (Channell et al. 2019), and current screening tools may fail to capture these. Again, practitioners must identify when behavioral symptoms are atypical in DS and signal ASD. Researchers have begun to modify the algorithms for commonly used ASD screening tools to assist practitioners in screening individuals with DS (Magyar

et al. 2012), but more research is needed. Identification of ASD in DS is important because individuals with DS and comorbid ASD likely will need different treatment to support optimal development than those with DS alone.

Risperdal

- [Risperidone](#)

Risperdal TM (Risperidone)

Elizabeth A. DeLucia

Yale Child Study Center, New Haven, CT, USA
Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Synonyms

[Risperidone](#)

Definition

Risperdal TM (generic name risperidone) is an atypical antipsychotic medication. It has been approved by the US Food and Drug Administration (FDA) to treat schizophrenia, bipolar disorder, and irritability associated with ASD. Risperdal TM is a dopamine and serotonin antagonist. Dopamine is a neurotransmitter related to reward pathways in the brain, while serotonin is involved in mood regulation. Risperdal TM works by blocking postsynaptic dopamine and serotonin receptors. Specifically, Risperdal TM binds to D₂ dopamine receptors and 5-HT_{2A} serotonin receptors, decreasing the amount of dopaminergic and serotonergic activity in the brain.

In 2006, Risperdal TM was the first medication approved by the FDA for symptoms associated with ASD in children and adolescents. (The FDA subsequently approved aripiprazole, another atypical antipsychotic, for treatment of symptoms associated with ASD in 2009.) Risperdal TM treats irritability associated with ASD and has been shown to decrease aggression, tantrums, and self-injury in children with ASD. There are significant side effects associated with Risperdal TM use in ASD; the most common side effects include weight gain and somnolence, but

other side effects such as drooling and involuntary movements have also been reported.

approved for the treatment of irritability in children with autism.

Indications

Risperidone is approved for the treatment of tics, aggression, and agitation. It is also

Clinical Use (Including Side Effects)

Risperidone was introduced into the American marketplace in 1994. It soon found its way into the clinic for the treatment of agitation, tics, and aggression. There were several small studies conducted in children with autism suggesting that it could be effective for the treatment of agitation and aggression. In the late 1990s, a large-scale study was launched showing that risperidone was far superior to placebo in reducing tantrums, aggression, and self-injurious behavior in children with autism. The study showed that, in addition to the short-term benefits of risperidone, the beneficial effects lasted for 6 months of observation. Indeed, when the medication was withdrawn in the placebo-controlled discontinuation phase of the study, subjects randomly assigned to placebo showed prompt return of the tantrums, aggression, and self-injurious behavior. The findings of this study were replicated and another study, which led to the approval by the Food and Drug Administration, of risperidone for the treatment of irritability (tantrums, aggression, and self-injurious behavior) in children with autism, ages 5–17.

Although risperidone is clearly effective in reducing these serious behavioral problems in children with autism, it is not without adverse effects. These studies demonstrated that risperidone is not associated with the commonly observed neurological adverse effects of the typical antipsychotic medications such as haloperidol, which has also been studied in children with autism. However, weight gain and metabolic changes have emerged as important concerns over the past decade. These concerns are also present for other atypical antipsychotic medications to varying degrees. The weight gain appears to be directly related to increased appetite. In the study published by the Research Units on Pediatric Psychopharmacology, half of the parents described increased appetite treated with risperidone under double-blind conditions. When asked

whether this increase in appetite was a problem, 25% of the parents reported that the increase of appetite was a new problem. The increased appetite was associated with approximately a 6-lb weight gain in 8 weeks compared to approximately 1 lb in the placebo group. Over the 6 months of observation, children treated with risperidone gained 12 lb.

Ritvo, Edward

Ariella Riva Ritvo
Child Study Center, Yale School of Medicine,
Yale University, Los Angeles, CA, USA

Name and Degrees

Edward R. Ritvo, M.D.

Major Appointments (Institution, Location, Dates)

- B.A., Social Anthropology, Harvard University, Cambridge, MA, 1951
- M.D., Boston University School of Medicine, Boston, MA, 1955
- Internship, Massachusetts Memorial Hospital, Boston, MA, 1956
- Psychiatry Residency, Massachusetts Mental Health Center, Boston, MA, 1956–1958
- Teaching Fellow in Psychiatry, Harvard Medical School, Tufts Medical School, Boston, MA, 1957–1958
- Fellowship in Child Psychiatry, James Jackson Putnam Children's Center, Boston, MA, 1958–1959

Edward R. Ritvo: deceased.

- Chief, Closed Neuropsychiatric Section, US Army Brook General Hospital, Sam Houston, TX, 1958–1961
- Fellowship in Child Psychiatry, Reiss-Davis Clinic for Child Psychiatry, Los Angeles, CA, 1961–1962
- Instructor, Assistant Professor, Associate Professor, and Professor (now Emeritus), Neuropsychiatric Institute, UCLA School of Medicine, Los Angeles, CA 1962 to June, 2020

Major Honors and Awards

- The National Society of Autistic Children Annual Award for Scientific Achievement, 1974
- American Psychiatric Association, Blanche F. Ittleson Award, 1990
- American Academy of Child and Adolescent Psychiatry, George Tarjan Award, 1994
- International Society for Autism Research, Lifetime Achievement Award, 2010

Landmark Clinical, Scientific, and Professional Contributions

A prolific researcher and clinician, Dr. Ritvo has conducted pioneering studies in autism. His early work included new approaches to the definition of the condition, development of rating scales for autism, and studies of electrophysiology and neural systems. His work has also included epidemiological and genetic studies as well as pioneering work on neurochemical systems and potential pharmacological treatments. A member of the UCLA faculty for many decades, Dr. Ritvo has helped shape the careers of many researchers and clinicians.

Short Biography

Dr. Edward Ritvo graduated in Harvard College in 1951 and Boston University School of Medicine 1955 and completed Adult and Child Psychiatry training at Harvard Medical School. After serving as Chief of Fourth Army Psychiatry (Captain, US Army), he joined the faculty of

UCLA Medical School in 1960, where he pioneered multidisciplinary research on autism spectrum disorder in the areas of neurophysiology, neurobiochemistry, neuropathology, genetics, clinical diagnosis, and epidemiology. He is recognized as an international authority on autism spectrum disorder, has written three books and over 90 scientific articles in peer-reviewed journals, and has received awards for his research contributions from the American Psychiatric Association, the American Academy of Child Psychiatry, and the International Society for Autism Research. Edward R. Ritvo died on June 10, 2020.

Ritvo-Freeman Real Life Rating Scale

Deborah A. Pearson

Department of Psychiatry and Behavioral Sciences, University of Texas Medical School at Houston, Houston, TX, USA

Synonyms

Ritvo-Freeman RLRS; RLRS

Description

The Ritvo-Freeman Real Life Rating Scale (RLRS; Freeman et al. 1986) was originally designed as a direct observational measure for assessing treatment effects for individuals with autism in their natural setting. In this format, pairs of trained raters observed an individual with autism for 30 min in the same setting, at the same time of day, for 3 days, and reported the presence and frequency of a number of behaviors associated with autistic symptomatology in five different domains. The scale has been used to study treatment effects in both children with autism (e.g., Matese et al. 1994; McDougle et al. 2005; Ritvo et al. 1986) and in adults with autism (e.g., McDougle et al. 1996, 1998).

In the RLRS standardized procedure that was initially used by the Autism Network of the Research Units on Pediatric Psychopharmacology (RUPP), a room is set up with a parent chair that is surrounded by toys. The parent and child are escorted into the room, and the parent is provided with index cards that instruct the parent how they should interact with their child in specific ways. These instructions are designed to elicit reactions by the child with autism that can be used to code ratings for the 47 target behaviors. The parent and child are positioned about 10 ft. from one another, and the raters observe the interactions set up by the instructions. The raters typically observe behaviors from behind a one-way mirror (or from an observation suite), and the session is recorded.

During the 30-min observation period, the rater (s) notes the frequency of 47 individual target behaviors. At the end of the observation period, each item is rated on a 0–3 scale, reflecting the occurrence and frequency of the target behavior that was seen during the 30-min observation period: 0 = Never, 1 = Rarely (1–3 times), 2 = Frequently (4 or more times), and 3 = Almost always (occurred constantly throughout the observation period). Individual target behavior items are then grouped into the five scales: I. Sensory-Motor Behaviors (7 items), II. Social Relationship to People (9 items), III. Affectual Reactions (5 items), IV. Sensory Responses (16 items), and

V. Language (10 items). Scale scores are obtained by summing the scores of the individual items and dividing by the number of items on the scale. Scores on items reflecting appropriate behavior, e.g., item #3 on the Language scale (“initiates appropriate verbal communication”), are subtracted prior to the calculation of the mean score from scales II, IV, and V. The mean scores on the five scales are then summed to create an overall score.

Historical Background

As reported by Freeman et al. (1986), the RLRS was first developed as a measure of overall severity of autistic symptomatology. It was designed to be administered at repeated intervals both at baseline (i.e., before treatment is initiated) and then at subsequent intervals (i.e., after treatment is initiated).

Although two of the major goals in developing this instrument were that nonprofessional observers could be rapidly trained to use it and that interobserver agreement should be easily attainable, at least one multisite study (McDougle et al. 2005) reported unacceptable validity across different sites/raters. Due to concerns with unacceptable reliability across study sites, the RUPP network created a modified RLRS instrument that converted the original observational measure to a parent rating scale. The original five scales were retained in this parent instrument, and the individual items were rephrased so that parents could rate their child's behavior on a 0–3 questionnaire format.

Psychometric Data

Relatively little information was provided in the original (1986) article regarding the characteristics of the sample (e.g., age, IQ, gender) from which the psychometric data were generated. The authors state that the instrument is applicable to patients of varying symptom severity. Interrater reliability for experienced observers was assessed using correlational methods: Pearson correlations

ranged from .59 to .85 on the five scales and was .90 on the overall score; intraclass correlation ranged from .62 to .78 on the scales and was .83 on the overall score. Interrater reliability was predictably lower for novice observers.

In contrast, Matese et al. (1994) reported poor interrater reliability for Scale III (Affectual Reactions) and Scale IV (Sensory Response); they also reported that 14 out of 47 items had intraclass correlation coefficients below the acceptable level of .5. However, they also pointed out that reliability estimates may have been deleteriously affected by their small sample of children with autism ($n = 15$) and by their raters having had minimal practice using the RLRS with clients being rated.

Concerns about interrater reliability using direct observation method are particularly notable in multisite projects. As McDougle et al. (2005) report, despite extensive and repeated training of study personnel, as well as standardization of procedures, the RUPP network was unable to attain acceptable reliability across the five study sites on the original direct observational instrument.

Another potential psychometric concern with the RLRS is that because scores for appropriate behaviors are subtracted from subscales II, IV, and V, the resulting score on the subscale can be negative. Specifically, this situation can occur if the sum of the inappropriate behaviors (e.g., items 4–10 on the Language scale) is not higher than the sum of the appropriate behaviors (e.g., items 1–3 on the Language scale).

A particular strength of the RLRS is that the target behaviors that closely mirror core behaviors associated with autism. For instance, on Scale I: Sensory Motor Behaviors, the individual items include whirls, flaps, pacing, bangs/hits self, rocks, and toe walks. Another strength is that this autistic symptomatology can be assessed in a natural setting using the RLRS. However, given the concerns with interrater reliability across multiple sites/raters, to the extent possible, if the direct observation version of the RLRS is used, it may be advisable to employ the same rater across repeated administrations – a strategy employed by Tolbert et al. (2001).

Clinical Uses

This RLRS is not marketed commercially as a clinical measure. However, in addition to its use as a research instrument, its creators intended it to be used to assess response to intervention in a clinical setting – both within individual patients and among groups of patients. Ritvo et al. (1986) even reported anecdotally that parents had been trained to use the RLRS to track treatment response in the home setting.

The RLRS has been used to study a variety of medication and nonmedication treatments in individuals with autism, including risperidone (e.g., McDougle et al. 2005; Miral et al. 2008; Gencer et al. 2008), fluvoxamine (McDougle et al. 1996), fenfluramine (Ritvo et al. 1986), and casein-free/gluten-free diets (Hyman et al. 2010).

RJA/IJA (Initiating/Responding to Joint Attention)

Peter Mundy
Psychiatry and School of Education, UC Davis,
Davis, CA, USA

Definition

Before language develops, infants learn to communicate. One essential part of this involves learning to jointly attend to the same referent (object or event) with another person in social interactions. This development of the capacity for purposeful social attention coordination or *joint attention* develops slowly from early in the first year of life through childhood. Much like language, the development of joint attention in infancy is expressed in terms of both receptive and expressive forms (Mundy et al. 2009). *Responding to joint attention* (RJA) is the receptive form and refers to infants' ability to follow the direction of the gaze and gestures of others in order to share a common point of reference (Fig. 1a).

Once fully developed, RJA allows infants and toddlers to use others' gaze to identify the referent of their actions, such as language, or their intentions and feelings. Alternatively, *initiating joint attention* (IJA) is the expressive form and involves infants' use of gestures and eye contact to direct attention to objects, events, as well as to themselves. The function here is to use nonverbal bids to show or spontaneously seek to share a child's interests or pleasurable experience with others (Fig. 1). Both of these types of joint attention are behaviorally well developed by 9 months but continue to develop well into the second year. Their beginning point is less well understood but evidence suggests that the onset of RJA may be as early as 2–4 months of age (Mundy 2011).

Historical Background

The importance of joint attention in understanding autism stems in large part from its role in the social attention model of autism. This social attention model suggests that autism is characterized by atypical quantity or quality of attention to people in the first years of life. The attenuation of attention to people undermines the capacity of young children with autism to learn from and with other people. Hence, a paucity of social attention leads to an "early social learning disability." This contributes to deviations in the age-appropriate pace of social communication and cognitive development in children with this syndrome (see Fig. 2). Hence, social attention impairments have come to be considered a cardinal symptom domain of autism (e.g., Dawson et al. 2004; Mundy 1995; Schultz 2005). The causes of decreased early social attention are unclear. Nonetheless, they likely stem from atypical neural development and consequent differences in motivation, executive functions, or perceptual processes which typically serve to support or even promote attending to other people in early development.

Diminished social attention to people in autism is expressed in three domains: (1) impaired *social orienting* or the tendency to prioritize and deploy attention to people versus objects (Dawson et al. 2004; Klin 1991), (2) impaired *joint attention* or the capacity to readily coordinate visual, auditory, or mental attention with a social partner, which is often used to share affective experiences of objects of events with others (e.g., Mundy et al. 1986), and (3) impaired *face perception and processing* such as the capacity to process facial expressions of emotions (e.g., Schultz 2005). The study of all these domains has been vital to advancing the science of autism in the past two decades. However, perhaps the strongest direct evidence linking social attention deficits with social learning, social symptoms, and effective treatments for autism comes from studies of joint attention.

RJA/IJA (Initiating/Responding to Joint Attention), Fig. 1 Illustrations of different types of infant social attention coordination behaviors: (a) responding to joint attention – RJA, involving following another person's gaze and pointing gesture; (b) initiating joint attention – IJA, involving a conventional gesture "pointing" to share

attention regarding a room poster; (c_{1,2,3}) IJA, involving *alternating eye contact* to share attention with respect to a toy; (d) initiating behavior request, involving pointing to elicit aid in obtaining an out-of-reach object; and (e) responding to behavior requests, involving following an adult's open-palm "give it to me" gesture

The development of joint attention heralds a new stage of infant-caregiver interactions that facilitate social learning. For example, early language learning often takes place in unstructured, incidental situations where parents use an unknown word to refer to a new object. In such situations, infants are faced with a problem. How does an infant know which of the myriad potential referents in the field of view to attach to the word? Many processes help the infant to solve these problems, and one of these involves their use of

RJA and following the spatial direction of the gaze of their parent. This increases the likelihood of attending to the area of the environment that contains the correct word-object match, thus reducing referential mapping error in early word acquisition (Baldwin 1995). Infants' use of an IJA bid, such as a show, to spontaneously indicate interest in an object or event even more precisely delimits the referent for possible new word learning or information-gathering opportunities with caregivers. Thus, joint attention serves a

self-organizing role that optimizes social information processing in early, unstructured social learning interactions. Through joint attention, and other skills like imitation, young children play a vital and active or *constructivist* role in social learning.

Historically, it was Frank Curcio (1978) at Boston University who published the first observation that raised the hypothesis that children with autism may have a specific deficit in the use of joint attention which impedes their adoption of an active, constructivist role in social learning. Observing children in a classroom, Curcio noted that students with autism did not use eye contact and gestures to share the experience of an object or event with others (i.e., joint attention), even though they appeared to use eye contact and gestures for other forms of nonverbal communication such as requesting. Curcio's observation that children with autism exhibit a specific impairment in joint attention, relative to other preverbal communication behaviors, was ultimately replicated and extended by numerous studies. The first set of these studies indicated that joint attention impairments were characteristic of young children with autism *but not* young mental age-matched groups of children with other types of developmental disorders (Loveland and Landry 1986; Mundy et al. 1986).

Later, the importance of the distinction between IJA and RJA became apparent. Clinical research indicates autism is characterized by pronounced impairments in *both* IJA and RJA in the first 24–48 months of life. However, sometime after about 30 months mental age, many children with autism begin to improve in RJA skills but remain relatively impaired in IJA (Mundy et al. 2009). Hence, many children with autism seem to improve in the face processing and gaze processing necessary to track and respond to gaze of others but continue to be relatively impaired in using gaze or gestures like showing to initiate episodes of shared attention and experience with others. This observation is incorporated into current diagnostic systems where IJA impairment or “the lack of spontaneous sharing experiences with others, such as showing. . .” is a primary symptom of social impairment in both American and

European psychiatric nosologies, but gaze following is not (Mundy et al. 2009). Moreover, gold-standard diagnostic measures, such as the Autism Diagnostic Observation Schedule, recognize that measures of both IJA and RJA are useful in diagnostic algorithms for the youngest children; but for older children on the cusp of language development, only IJA measures are included in the diagnostic criteria (Lord et al. 2000). Hence, one current important hypothesis about autism is that it involves a disturbance of the spontaneous generation of social behaviors, as much as or more than a disturbance of the perception and response to the social behaviors of others (Mundy 1995).

Current Knowledge

Advances in the current knowledge of the role of IJA and RJA impairments stem from at least three areas of science: cognitive neuroscience, developmental science, and intervention research. Cognitive neuroscience has begun to provide insights into the development of joint attention that tie joint attention to psychological and neurodevelopmental theory on the etiology of autism. Current evidence suggests that the development of RJA and IJA functions is supported by common as well as distinct elements of a distributed frontal and parietal neural network (e.g., Redcay et al. 2010; see Fig. 2). This is important because theory and research suggest that children with autism may be most vulnerable to complex cognitive developments and processes that require connectivity and the rapid transmission, comparison, and integration of information across distal frontal and cortical networks (e.g., Courchesne and Pierce 2005). Thus, it may be that joint attention impairments are an early expression of the developmental vulnerability in complex-distributed cognitive processes in autism.

It is also the case though that theory and research have long suggested that IJA impairments in autism may arise from disturbances in the motivation to attend to people or to spontaneously share experiences with other people (Mundy 1995). Recent cognitive neuroscience

RJA/IJA (Initiating/Responding to Joint Attention), Fig. 2 Illustrations of recent imaging data on the distributed cortical processing network involved in joint attention. (a) On the left-hand side of the figure are illustrations from a paper by Redcay et al. (2010) that depict the frontal and parietal systems involved in joint attention, as well as the patterns of cortical activation that distinguish initiating

and responding to joint attention behaviors. (b) On the right-hand side of the figure are illustrations from a recent paper by Leonhard Schilbach et al. (2010) that show the distributed joint attention network and raise the seminal possibility that network activation in the striatal cortex, associated with the processing of positive stimulus reward value, distinguishes the neural network of IJA from RJA

lends support to this hypothesis with the observation that one element of the neural network that distinguishes IJA and RJA is the contribution of frontal striatal reward networks to the former but not the latter (Schilbach et al. 2010, see Fig. 2).

The significance of IJA and RJA impairments in autism, however, may be best understood in the context of studies on the relations of joint attention to human learning and development. Indirect support for this connection has come from observations from developmental studies that indicate that frequency with which infants engage in joint

attention is positively and significantly related to their language acquisition, even when variance associated with general cognition is controlled (e.g., Mundy et al. 2009). Joint attention is also associated with the depth of information processing and recognition memory in infants, as well as with individual differences in childhood measures of IQ, self-regulation, and social competence (Mundy et al. 2009). In autism, IJA development has been observed to predict social development and RJA to predict language development into later childhood and even adolescence

(Sigman and McGovern 2005; Sigman and Ruskin 1999).

The connection between IJA, RJA, and learning in autism becomes even clearer in the context of information provided by early intervention research. Several experimental studies have reported observations that suggest that early intervention to improve the initiation of joint attention leads to a cascade of enhanced social learning effects in young children with autism (Kasari et al. 2008; Jones et al. 2006; Whalen et al. 2006). For example, Kasari et al. (2008) have reported a sequence of findings from a randomized control trial of an intervention to improve IJA development in 3-year-olds with autism. All the children in this study were enrolled in a comprehensive 1-year program of 30 h per week of intervention based on applied behavior analysis (ABA). Thirty-nine children in this program were randomly assigned to an additional brief 5- to 6-week course of 30 min of intervention to increase IJA development, and 17 children were assigned to an ABA-only treatment comparison group. The results indicated that the IJA treatment not only improved joint attention development in the treatment group but also boosted language learning and longer term outcomes for young children relative to the improvements children made in ABA alone.

This is not to say that RJA is not important in social learning. Another research group examined the degree to which language improved in a sample of 29 4-year-olds with autism who were in a variety of communication-based interventions (Bono et al. 2004). On average, children in this study received 24 h of intervention per week for 1 year. Children were enrolled in a variety of intervention modalities including ABA, speech and language therapy, occupational therapy, social skills interventions, sensory integration, and various combinations of these interventions. As a group, the 29 children displayed modest gains in language over the year, and language gains did not appear to be “dose related.” That is, greater language gains were not observed for children receiving more hours of intervention per week. However, on further inspection, Bono et al. (2004) observed that the group could be divided in

children with well-developed RJA and poorly developed RJA at the beginning of the study. Only the former group displayed significant language gains after 1 year and, within this group of children with more hours of intervention, displays greater gains in language. Thus, consistent with the social learning hypothesis of joint attention in autism, the presence or absence of RJA skill moderated language learning and sensitivity to intensity of intervention in this sample of children.

Future Directions

Social Cognition and Joint Attention

Sometime, people confuse joint attention with social cognition and neglect the role that joint attention plays in social learning. The social cognitive model of joint attention proposes that as infants monitor and represent their own goal-related intentional activity, they also monitor and represent the goal-related behavior of others (Tomasello et al. 2005). The early development of social cognition at about 9–12 months allows infants to integrate these two sources of information over time, and infants become able to impute the conditional proposition that if self-intentions lead to goal-related behavior, then goal-related behavior in others must follow from their intentions. Thus, this model suggests that social cognition is necessary for the development of functional joint attention in infancy. Furthermore, social cognition is thought to be equally common to all types of joint attention. Therefore, initiating and responding to joint attention should be highly correlated in development.

Research supports elements of the social cognitive model. In one revealing study, testers either turned their heads with their eyes open or turned their heads with eyes closed in gaze following trials presented to 9-, 10-, and 11-month-olds (Brooks and Meltzoff 2002). The task for the infants was to respond to joint attention and turn their attention in the direction of the gaze or head turn of the tester. All the children performed equally well in the “eyes open” condition. However, in the “eyes closed” condition, the 10- and 11-month-old infants rarely followed the testers’

head turns, but the 9-month-olds followed at a rate comparable to the eyes open condition. Thus, the 10-month-olds were able to inhibit following in this condition presumably based on a social cognitive awareness of the meaning of the referential intent of visual gaze. However, the 9-month-olds were not able to inhibit their responding behavior because they lacked this aspect of social cognition.

Of course, Brooks and Meltzoff's (2002) data also indicate that 9-month-olds engage in joint attention behavior *before* they fully develop aspects of social cognitive awareness. Indeed, 9-month responding to joint attention predicts 24-month language, attesting to the functional validity of its measurement at that age (Mundy et al. 2009). These observations challenge the social cognitive model. So do observations that initiating and responding to joint attention are not highly correlated in development, display different patterns of age-related growth in infancy, and have unique associations with subsequent development (Mundy et al. 2009). An alternative to the social cognitive perspective appears to be needed to account for these observations.

Mundy et al. (2009) have proposed one such alternative in which joint attention enables social cognitive development. Accordingly, joint attention is an outcome of two interacting attention regulation systems described by Michael Posner and his colleagues. One is the posterior orienting and perceptual attention system, and it plays a primary role in responding to joint attention development in infancy. This relatively involuntary system begins to develop in the first months of life and prioritizes the capacity to orient in the direction of biologically meaningful stimuli. It is supported by the parietal and superior temporal cortices (Fig. 2b), which serve aspects of representational development, imitation, and the perception of the eye and head orientations of others, as well as the perception of spatial relations between self, other, and the environment. The neural substrates and functions of this system are common to many primates. Shorthand for one goal-related cognitive output from this system is the understanding that "*where others' eyes go, behavior follows*" (Jellema et al. 2000).

Alternatively, initiating joint attention is supported by the later developing anterior attention system. This system controls volitional, goal-directed attention allocation that is constrained and corrected by reward-related self-appraisal of behavior. It involves a neural network that includes the frontal eye fields, prefrontal association cortex, orbital frontal cortex, and anterior cingulate. This system (e.g., anterior cingulate) also regulates the integrated activity across the anterior and posterior attention systems. This integration yields the distinct form of human attention we call joint attention (Mundy et al. 2009). As previously noted (Fig. 2), imaging data attest to the integrated activation of the anterior and posterior systems in human joint attention. Moreover, this joint attention network has much in common with the neural substrates of social cognition (Mundy et al. 2009).

Shorthand for an initial cognitive output from the anterior system is a *self-awareness* of intentional attention control and the understanding that "*where my eyes go, my successful behavior follows*." Mundy et al. (2009) suggested that an executive function of the anterior attention system integrates internal information about self-initiated goal-related attention deployment (where my eyes go, my behavior follows) with external information from posterior system processing of the attention and behavior in others (where others' eyes go others' behavior follows). As this integrative processing matures in social interaction, a fully functional adaptive human social cognitive system emerges. Thus, the social coordination of *overt* aspects of visual attention early in infancy provides information and experiences that nourish the development of the human capacity for social coordination of *covert* aspects of attention (i.e., social cognition), such as when social partners share attention to psychological phenomena including ideas, intentions, and emotions (Mundy et al. 2009).

Elements of this perspective are consistent with current social cognitive models. However, an explicit tenet here is that the rapid, real-time functional interactions and maturation of a distributed cortical attention network make a

fundamental contribution to the human development of social cognition. This notion owes much to Gerald Edelman's (2006) long-standing hypothesis that synchronous or "reentrant" firing of distal cortical neural groups is vital to consciousness and self-conscious systems. This model also recognizes that processes that affect the organization, accuracy, and speed of integrated processing, within or across the anterior and posterior attention systems, may contribute to phylogenetic or human developmental differences in joint attention and social cognition. Finally, to be fully realized, integrated processing of the anterior-posterior systems requires practice with sharing attention early in life. Thus, in this model, practice with joint attention in the first 9 months of life is thought of as a major *contributor to* rather than a *product of* the development of social cognition. Consequently, early joint attention impairments are thought to lead directly to a form of social learning disability which has a negative impact on language learning as well as social cognitive and social skills development in childhood (for more details see Mundy 2011; Mundy et al. 2009).

Definition

Robot-assisted therapy is a promising area of translational neuroscience for children with autism spectrum disorders (ASD). The robot-assisted cognitive behavioral therapy (RA-CBT) is a robot-assisted therapy focused on cognitive behavioral therapy (CBT), which shows promising evidence of efficacy and represents a viable intervention for children with ASD. This type of treatment consists of a human-assisted social robot acting as an intervention mediator to increase the emotional competence and to improve the socio-emotional understanding skills in children with ASD. RA-CBT can be used as a complementary therapy for ASD children with the potential to reduce the workload of the therapist and to improve the social skills.

Historical Background

Heterogeneity in clinical symptoms is the main characteristic of children with ASD, including high rates of comorbid medical conditions (e.g., sleep disorders, gastrointestinal dysfunction, autoimmune disorders), neurological conditions (such as seizures and sensory and motor system abnormalities), and psychiatric disorders (such as attention deficit hyperactivity disorder and anxiety).

Deficits in social cognition and emotional regulation are common in children with ASD (Leekam 2016; Berkovits et al. 2017). Impairments in social awareness, perspective-taking, and implicit theory of mind are reported regardless of their cognitive and language abilities (Leekam 2016), as well as difficulties in metacommunication and in understanding social contexts or maintaining reciprocal conversation (Sharma et al. 2018). Emotional dysregulation provokes social and behavioral difficulties over time (Berkovits et al. 2017), as well as issues in social success, academic readiness, and prosocial behaviors.

Despite ASD is a neurobiological disorder, behavioral treatments are currently the main tool for reducing disability and comorbidity because these are usually focused on maximizing the ability in social skills and communication (Lai et al. 2014). Social situations in particular contain a great amount of information, overwhelming ASD children, who have difficulty deciding which pieces of information are relevant. It has been suggested that the perception of biological motion is impaired in ASD, generating a cascade of consequences for social development (Klin et al. 2009).

Generally, various behavioral approaches exist for ASD patients and are classified into (Lai et al. 2014) (i) comprehensive applied behavioral analysis-based intensive intervention; (ii) targeted skill-based intervention (training in joint attention, teaching social skills, and social skill training); and (iii) targeted behavioral intervention for anxiety and aggression (cognitive behavioral therapy).

In particular, the treatment approach named cognitive behavioral therapy (CBT) is a psychotherapeutic method used in clinical settings to treat ASD, as well as other mental health disorders. In particular, CBT protocols contribute to improve the core evidences of ASD, i.e., social-behavioral adaptations, social skills, social anxiety, emotional regulation and aggression, co-occurring emotional and behavioral symptoms, and others.

All the abovementioned treatments promote the development of intelligence, communication, and adaptive function, as well as language, daily living skills, and socialization. However, ASD patients show marked heterogeneity at genetic,

behavioral, etiological, and pathophysiological levels, which interfere with the efficacy of intervention programs (Maglione et al. 2012). Moreover, it is well known that ASD individuals engage more successfully in social interactions if social information is presented in an “attractive” manner (Quirnbach et al. 2009). Therefore, there is a critical need for tools capable of increasing the effectiveness of standard (cognitive-) behavioral therapies (as well as reducing their cost).

The last two decades have seen the emergence of some technology-based therapies, including computer programs, virtual reality, and robot-assisted protocols. Robot-assisted therapy has gained attraction in the past few years to become an emerging and promising application area where researchers and clinicians have developed models with a wide range of appearances, features, and functional capabilities that draw from expertise in fields such as engineering and clinical psychology (Sartorato et al. 2017). Robot-mediated intervention studies have shown positive outcomes in areas of research such as social communication, joint attention, imitation, and social behaviors (Pennisi et al. 2016), in teaching with robots as an emulated peer (Yun et al. 2017), and in learning of socio-emotional understanding skills (Marino et al. 2020). Again, the robot-assisted therapy approach has naturally become more attractive since this is based on that simple observation that a child that shows no eye contact (the most basic social behavior) with a therapist could be successfully stimulated by social robot (Pennisi et al. 2016).

This kind of behavioral approach has two fundamental advantages: (a) the ability of robot to adaptively “learn” both inter-individual differences at one time point and intraindividual differences over time, thus partially overcoming the limitations due to clinical heterogeneity, and (b) the opportunity to record objective data during therapy. This latter characteristic is vital to characterize the progress of the child providing quantitative data about the developmental process and to partially automate the currently manual analysis (Thill et al. 2012).

Recently, social robots are considered effective tools to support interventions with group-based CBT for young children with ASD aimed at the development of higher-order emotional behavior

and cognition. In a first randomized controlled trial, a RA-CBT method was applied within an emotional understanding and social cognition treatment protocol for children with ASD (Marino et al. 2020). The RA-CBT study reported positive results on the efficacy of a robot-assisted therapy as effective augmentative mediator in CBT protocols for socio-emotional understanding, through a social robot able to provide cues, prompts, and reinforcements. Significantly, such a study has shown an increased ability in the experimental group to understand the beliefs, emotions, and thoughts of others.

Current Knowledge

Robot-assisted intervention demonstrated clear evidence in motivating the child in social situations (Pennisi et al. 2016), as other nonhuman agents supporting the therapy with children with ASD. Preliminary evidence of efficacy in assisting in the diagnostic process is reported. Other robot-assisted intervention studies have shown reduced repetitive, stereotyped behaviors, and more spontaneous language in children with ASD engaged in social interactions with a robot (Thill et al. 2012; Pennisi et al. 2016), showing better performances with a robot partner rather than a human one. Meaningfully, it has been demonstrated that robot-assisted intervention provides therapists and researchers a means to connect with ASD subjects in an easier way improving social communication skills, such as eye contact, joint attention, imitation, turn-taking, self-initiated interactions, emotion recognition, and triadic interactions (Bird et al. 2007; Cabibihan et al. 2013; Kim et al. 2013; Pennisi et al. 2016).

Anyway, clinical validation studies of robot-assisted protocols in enough heterogeneous clinical samples are still undergoing. Currently, the feasibility study of Mengoni et al. (2017) study clinically tested the effectiveness of a humanoid robot to support social skills in young children on the autism spectrum. The RCT study of Yun et al. (2017) administered a robot-assisted discrete trial teaching protocol to improve basic social skills. The RCT study of

Marino et al. (2020) administered a RA-CBT to improve socio-emotional skills in children with ASD. In term of emotional comprehension, this study has shown how a short robot-assisted cognitive behavioral protocol of only 15 h may shift the children's skills to the normative range (Marino et al. 2020). Only preliminary but promising studies are applying neuroimaging tools for extracting neural hallmarks of robot-assisted treatment with ASD subjects (Jung et al. 2016; Chaminade et al. 2012; Goulart et al. 2019). Preliminary evidence with portable EEG system (Chaminade et al. 2012) has shown significant brain activity changes in ASD child's brain before, during and after social robot interaction.

The most widely used artefacts for robot-assisted intervention with ASD are listed in Table 1.

Future Directions

RA-CBT can effectively be adopted in boosting learning of socio-emotional understanding skills. Actually, in order to strengthen the clinical validation of RA-CBT, the sample size must be increased. It is worth mentioning that in the robot-assisted state-of-the-art just the attentional engagement with the robot is measured. A future direction must be dedicated to stimulating quantitatively comparison of other variables, i.e., the number of exchanges, the contingency of reinforcements, the consistency of the stimuli, the engagement of a human therapist, and other measurements of administration reliability. Moreover, effectiveness of RA-CBT in studies dedicated to inferring differences in gender engagement and gender socio-emotional understanding skills should be envisaged. Moreover, it should be interesting to investigate any possible protective effect of RA-CBT-based emotional skills training against the negative social feedback experienced by almost all children with ASD during childhood.

From a neuroscientific point of view, significant progress has been made in understanding the multidimensional nature of ASD and the possible trajectories of neural progression (Masi et al. 2017). In particular, one of the targets to unravel

Robot-Assisted Cognitive Behavioral Therapy for Young Children with Autism Spectrum Disorders,
Table 1 Most used artifacts for robot-assisted intervention with ASD

Name	Company	Type	Characteristics
NAO	Aldebaran robotics company	Humanoid	Body in plastic with 25 DoF (4 joints for each arm; 2 for each hand; 5 for each leg; 2 for the head and one to control the hips). This is able to capture a lot of information about the environment using sensors and microphones. Nao can speak and assure a certain degree of non-verbal communication
QTrobot	LuxAi	Humanoid	QTrobot is an expressive little humanoid robot, designed and built based on scientific approaches to assist in teaching new skills to learners with autism and special educational needs. QTrobot supports learners to practice cognitive, social, communication, and emotional skills and helps them benefit more from educational sessions.
KASPAR	University of Hertfordshire's adaptive systems research group	Humanoid	Minimally expressive with 6 DoF on the head and neck, 6 on the arms, 2 in the eyes. Its face is a silicon-rubber mask. KASPAR's face can show a range of simplified expressions but in a less complex way than real human face. It is able to respond to the touch of children and can move its arms, head, and eyes
FACE	University of Pisa	Humanoid	It is a passive body with an active head. It has 32 motors to simulate and modulate six basic emotions (happiness, sadness, surprise, anger, disgust, and fear). FACE is not able to speak; it has microphones and cameras by which it can analyze the emotional reactions of individuals, react to them, and store all data
Tito	Wikifactory	Humanoid	It uses wheels to move, has two arms that can be moved up and down; it can turn its head right and left and up. It has two eyes and a mouth by which it can smile. Tito can speak by prerecorded vocal messages. Tito has a small microphone camera and can also be controlled by a wireless remote control
Bioid robot	ROBOTIS	Humanoid	Bioid robot can be assembled in various configurations (scorpion, spider, dinosaur, puppy, and humanoid robot). It can have 18 or 16 DoF; thus it has a wide body mobility, but its face is inexpressive. It does not speak
Pleo	Ugobe Inc	Animal-like	Dinosaur pet toy with 16 DoF, a camera-based vision system for light detection and navigation, microphones, touch sensors, ground foot sensors, force feedback sensors, an orientation tilt sensor for body position. It is able to move itself autonomously and can express emotions by motions and sounds in response to children's touch or various interactions such as caresses or giving food
LEGO	NXT	Toy	This is a programmable robotics kit developed by LEGO. The main component (NXT brick) can receive input from a maximum of 4 sensors and controls 3 motors. It can reproduce sampled sounds

the etiopathogenesis of ASD is the identification of potential neuro-endophenotypes (Gottesman et al. 2003), i.e., measurable neural system related subclinical heritable biological markers or behavioral traits that are internal phenotypic expressions

of a genotype. The advent of functional and structural neuroimaging techniques has provided a very powerful method to mapping the neural correlates of ASD-related subtypes, developmental trajectories, or progressive degeneration (Lau

et al. 2019). Through neuroimaging studies, a lot of neuro-endophenotypes have been proposed for ASD patients (Mahajan and Mostofsky 2015; Ruparel et al. 2017).

The introduction into clinical practice of robot-assisted therapy with ASD will lead to the adoption of effective applied neuroimaging tools able to identify the neural effects of such a treatment in different ASD-related subtypes while contributing to understand neural ASD profiles and pathophysiological mechanisms. Although the endophenotype-oriented neuroimaging research approach applied to robot-assisted therapy is in its relative infancy, it is definitely promising for future directions.

Definition

Autism Spectrum Condition (ASC) is considered one of the developmental disorders with the most pervasive and enduring impact on the whole family system. Studies have revealed a number of factors that are predictive of positive and negative family adaptation outcomes. Among these, the influences of sociodemographic and child characteristics on adaptation have been established. However, part of the family outcomes are not

explained by these factors but by parental and couple variables (García-López et al. 2016a, b).

Among parent resources and characteristics, studies highlight the importance of coping strategies and cognitions, such as sense of coherence, parental self-efficacy, or perception of positive contributions of disability in predicting positive adaptation outcomes. In the general population, couples' thoughts, feelings, and behaviors spread from one partner to the other; in the context of a stressful situation, these reciprocal effects might become even stronger. Couples raising individuals with ASC experience heightened levels of stress compared with controls and have to confront vital decisions for their children; therefore, it is expected that the couple relationship becomes a crucial factor affecting parents' psychological adaptation (García-López et al. 2016b). From a family systems perspective, the couple relationship is regarded as the nucleus around which the family functions and it has a pivotal role in creating a positive family environment (Minuchin 1985). Paradoxically, raising an individual with ASC can be both a challenging and rewarding experience. Despite reported challenges, many couples adapt positively to raising a child with ASC. This is consistent with family resilience theories, which postulate that adverse circumstances can lead to personal and relational transformations through the discovery of untapped resources and strengths.

Traditionally, the literature on family adaptation has focused on the negative impact of ASC on the couple relationship, with numerous studies describing relationship dissatisfaction and higher divorce or separation rates when compared with families without individuals with ASC (Hartley et al. 2010). However, research is increasingly highlighting the role of the couple relationship as a resource in families managing the challenges associated with raising an individual with ASC. This situation can create new opportunities for the couple to work together and share experiences that bring them closer and help them find new purposes, points of view, or values in life. In this context, the role of relationship satisfaction emerges as a key factor in the process of parental coping among families raising individuals with ASC.

Historical Background

From the general theories of stress and coping (Lazarus and Folkman 1984) and from models of family adaptation (McCubbin and Patterson 1983), different studies have reported robust evidence that shows that coping strategies play a protective role in families of individuals with ASC adaptation outcomes (Dabrowska and Pisula 2010; Hastings et al. 2005a). Coping strategies include behavioral or cognitive efforts aimed at reducing stress levels (Lazarus and Folkman 1984). Many classifications of coping strategies have been proposed. Among these, individual coping and dyadic coping have been two of the more explored methods of coping with stress.

Individual coping has been widely researched and is usually divided into problem or emotion-focused strategies. In the general population, emotion-focused coping (e.g., avoidance, engaging in ruminating, blaming oneself) has been positively correlated with health problems (e.g., anxiety and depression), whereas problem-focused coping (e.g., time management and obtaining social support) has been negatively correlated with these conditions. Within families raising children with ASC, the same pattern has been found, as parents who adopt active avoidance coping strategies, such as denial, distraction, or guilt, report more stress than those who implement positive and problem-focused strategies.

In contrast, dyadic coping has been relatively neglected, even though the literature on ASC-related parental adaptation recognizes the couple relationship as a primary source of support. In particular, in couples parenting individuals with ASC, the partner becomes a key source of both emotional and instrumental support for addressing the additional parenting demands associated with the disorder (García-López et al. 2016a). From a systemic-transactional perspective, dyadic coping involves coping strategies aimed at maintaining or restoring the structural, functional, behavioral, emotional, and social balance of the whole dyadic system, as well as the equilibrium of each partner. This theoretical framework is based on two key assumptions: first, stress and coping represent a dyadic

(systemic) phenomenon; second, dyadic coping with stress includes both stress expression and dyadic support. Two types of stress can be differentiated: relationship stress and external stress. The former is derived from the relationship as a result of differing goals or desires, whereas the latter starts outside the relationship due to work strains or conflicts. Within this framework, dyadic coping is considered one partner's attempt to help reduce the external stress perceived by their partner and a common endeavor to cope with stress that originates inside the relationship. The stress coping process is regarded as a sequence consisting of stress expression by the stressed person, the perception of stress by the partner, and the partner's coping reaction to the stressed person's behavior (Bodenmann 2000).

Dyadic coping can be either positive or negative. Positive forms of dyadic coping refer to supportive dyadic coping (such as providing practical advice or offering empathic understanding), common dyadic coping (such as joint problem solving, sharing feelings, or relaxing together), and delegated dyadic coping (such as one partner explicitly asking the other for support and consequently agreeing a new division of tasks). Negative dyadic coping includes hostile dyadic coping (such as distancing, mocking, or minimizing the seriousness of the partner's stress), ambivalent dyadic coping (such as one partner supporting the other reluctantly, as if their contribution was unnecessary), and superficial dyadic coping (such as asking questions about the partner's feelings without listening or providing support that lacks empathy) (Bodenmann and Cina 2005). The type of dyadic coping strategies used depends on variables such as the partner's individual and dyadic competences, motivational factors, and the characteristics of the situation in which the stress occurs. Dyadic coping is associated with the partner's level of relationship quality (Bodenmann 2000), relationship stability, and communication behavior (Bodenmann and Cina 2000). Effective dyadic coping not only reduces stress and improves partnership well-being but also strengthens a feeling of "we-ness" in the partners.

The concept of dyadic coping has been argued to be especially relevant to the prevention of

relationship deterioration and marital therapy. This idea has been supported by dyadic coping being strongly associated with partnership satisfaction. According to Bodenmann (2005), the relationship between dyadic coping and marital satisfaction can be facilitated through two separate mechanisms. First, dyadic coping works as a moderator between stress and partnership satisfaction. Second, dyadic coping strengthens feelings of mutual trust and intimacy, and the cognitions that the relationship is helpful and supportive.

In the general population, stress, dyadic coping, and the couple's relationship are related in multiple ways. First, stress reduces the time partners spend together, which implies having less time for dyadic coping. Second, stress decreases the quality of dyadic communication. Under stress, couples use more negative communication patterns, which are in turn predictive of poor relationship functioning and divorce. Third, chronic stress increases the risk of physical and mental health problems, limiting the opportunities for pleasant activities, confronting equity of roles between the partners, thus reducing marital satisfaction. Chronic stress can also originate outside the couple and spill over the relationship, decreasing the quality of dyadic coping. So, the more effectively each partner copes with external stress, the more they can reduce the probability of spill-over, protecting the couple's relationship from the impact of external stress. Consequently, both individual and partnership coping are considered to be protective factors of relationship satisfaction (Bodenmann 2005).

In summary, there are many ways of coping with stress. Dyadic coping, rooted in the transactional stress and coping theory, and nourished by family adaptation models and empirical studies, is one of these methods. This type of coping involves managing stress as a couple and is strongly associated with relationship satisfaction.

Relationship Satisfaction and Coping throughout its Lifespan

In the general population, a U-shaped pattern of partnership happiness over its duration has been described: younger and older partners are more

satisfied with their relationship when compared to those who are middle-aged. This decrease in relationship quality in non-ASC families is usually linked to the arrival of children, which often involves spending less time together, experiencing more conflicts, or having to make more decisions for couples (Landis et al. 2013; Hock et al. 2012).

Having a child with special needs complicates the transition to parenthood by increasing parental stress and anxiety. This transition sets a period characterized by an increased focus on the needs of the child, to the detriment of the needs of the couple. The couple's relationship often suffers due to the intense demands and energy required to meet the special child's needs. This change in focus away from the relationship may put the couple at risk for problems, as they might not share enough time to grow together as a couple and so experience increased stress in their lives.

Couples raising an individual diagnosed with ASC may experience high levels of stress, which is linked to lower relationship satisfaction. The increase in stress levels begins at the initial diagnosis stage and continues throughout the different stages of the life cycle, since each stage presents different challenges (Pozo and Sarriá 2015). As a result, it is not expected that the U-shaped pattern that occurs in the general population will be reproduced in families raising individuals with ASC. Evidence suggests a continued decline in relationship satisfaction through childhood and across the child's transition to adulthood (Hartley et al. 2012), a period when other parents are usually enjoying an upturn in satisfaction.

In contrast, some authors have regarded ASC as a crucible for parents, with three different phases in the course of the couple's relationship: the ASC crucible, tag team, and deeper intimacy and commitment. The first phase (ASC crucible) is considered a test for the couple's relationship as the child is regarded as a stressor and parents describe a dichotomous reaction: either fight for the relationship or end it. During the second phase (tag team), parents are focused on their parenting role, which requires reorganizing family and professional roles, and the couple's relationship is regarded as secondary. The last phase (deeper

intimacy and commitment) involves renovating the marital commitment as parents realize that looking after the relationship is beneficial to the ASC child (Hock et al. 2012).

Current Knowledge

Findings regarding the role of relationship satisfaction on parental coping in families raising individuals with ASC draw a paradoxical picture. Taking care of an individual with ASC places an additional stress on the couple's relationship, which challenges its stability and capacity to cope with the situation. Relationship satisfaction may serve as a protective factor that enhances positive parental coping and adaptation.

In addition to the usual relationship and external stress that characterizes any couple, parents raising individuals with ASC have to address new sources of stress derived from managing the practical, emotional, and financial demands associated with ASC. Thus, parents of individuals with ASC experience numerous challenges both as individuals and as couples that may change their everyday life and long term outlook. Parents raising individuals with ASC present more psychological problems such as stress, anxiety, or depression, lower dyadic consensus, and lower levels of relationship satisfaction compared with parents of typically developing children (Hayes and Watson 2013).

The cumulative stress posed on a relationship could ultimately lead to its dissolution. However, findings are mixed when it comes to divorce rates, as some studies show it is higher than in the general population (Hartley et al. 2010), whereas other studies have found no significant differences (Freedman et al. 2012). Conversely, relationship satisfaction may not be as drastically undermined by the challenge of rearing a child with ASC as has commonly been supposed. Rather than considering relationship satisfaction as an outcome measure that might be compromised as a consequence of dealing with ASC, the quality of the relationship is increasingly being regarded as a protective factor mediating the link between the child's disability and parents' emotional well-

being. Particularly, couples who report relationship satisfaction also report less parenting stress, greater use of positive dyadic coping strategies, and less use of negative dyadic coping strategies than couples who are dissatisfied in the relationship with their partner. Satisfied couples are more likely to engage in positive rather than negative dyadic coping strategies than dissatisfied couples (Sim et al. 2017). Conversely, positive dyadic coping contributes to maintaining relationship satisfaction, which in turn positively impacts parental adaptation (García-López et al. 2016a). Consequently, relationship satisfaction and positive dyadic coping are bidirectionally associated and act as protective factors in the process of parents' psychological adaptation.

Future Directions

Despite the importance of relationship satisfaction in family and child outcomes, few studies have explored its role as a coping strategy in the process of parental adaptation. Consequently, there are several implications regarding relationship satisfaction and coping in parents of individuals with ASC for the future at both the research and clinical levels.

Future research should prioritize family-centered approaches, since they are considered to be best practices. Special attention should be paid to the relationship as a protective factor in future empirical studies, as it has been associated with improved child behaviors, reduced stress, and positive adjustment in families raising individuals with ASC (Benson and Kersh 2011; Hartley et al. 2012). Another field of research that merits further exploration refers to sex differences regarding the role relationship satisfaction on parental coping. Findings so far suggest that mothers use different individual coping strategies to manage the stress derived from ASC when compared to fathers (Hastings et al. 2005b), but it remains unclear what role sex plays when the couple relationship is regarded as a method to cope with stress.

On the clinical level, as couples raising individuals with ASC are considered to be at high risk

of poor relationship satisfaction, it is crucial for clinicians to evaluate and monitor the quality of the couple's relationship, providing specific psychoeducation programs for couples. Professionals should raise awareness about the importance of maintaining the couple relationship and enhancing dyadic coping during stressful times. Specifically, the programs should be aimed at training dyadic coping strategies and strengthening relationship satisfaction, which are both variables that can be modified through intervention. Special attention should be paid to gender differences and needs when designing and implementing these family-centered interventions. In summary, in an era when family involvement in treatment programs is pivotal, looking after the partnership well-being should be a prerequisite to implementing any parent-mediated intervention.

Overall, despite an increased risk of poor relationship satisfaction in couples raising individuals with ASD, evidence shows that many couples overcome this situation and grow stronger, taking advantage of the couple relationship as a coping strategy.

Role Release

Cheryl Smith Gabig

Department of Speech, Language, and Hearing Sciences, Lehman College/The City University of New York, Bronx, NY, USA

Synonyms

Child and family-centered intervention; Collaborative consultation; Collaborative intervention; Collaborative teaming; Cross-training; Interdisciplinary assessment and intervention; Intervention activity; Multi-skilling; Transdisciplinary assessment and intervention; Transfer of function

Definition

Role release is the transfer or sharing of a specific task, activity, or intervention practice usually

performed by a discipline-specific member of the educational or therapeutic team to another person. The task or activity delegated should meet certain conditions: the task or activity does not require discipline-specific training or licensure to perform, the task or activity is trained and the appropriate implementation of the activity is supervised by the responsible team member, and the task or activity is done on behalf of a specific child under the direction of the professional. Examples of areas of role release or cross-training include (1) management and administrative tasks related to programmatic activities such as scheduling and quality improvement; (2) nonclinical skills and activities including parent education, case management, and technical writing; (3) basic care activities including activities of daily living, monitoring of medications and vital signs, and noninvasive medical activities such as suctioning; and (4) clinical specific activities including intervention activities that can be cross-trained and monitored by the professional such as parent-led language stimulation and cross-disciplinary implementation of activities that facilitate and support a discipline-specific goal.

The concept of role release or cross-training of other personnel to manage or provide aspects of management and intervention activities has its roots in both health care and education. Various terms are utilized by the different disciplines to describe the collaborative effort in sharing responsibility for a child's therapeutic or educational needs including *collaborative consultation*, *collaborative intervention*, *collaborative teaming*, *interdisciplinary assessment and intervention*, *transdisciplinary assessment and intervention*, and *child and family-centered intervention*.

Romanian Adoptive Children

Nurit Yirmiya and Ifat Seidman
Department of Psychology, The Hebrew
University of Jerusalem, Jerusalem, Israel

Definition

Some of the thousands of children (about 10%) who were adopted by Western families from destitute and overcrowded Romanian institutions during the 1990s revealed autistic-like symptoms pertaining to the triad of core autism deficits in social interaction, communication, and interests/activities. Although it is well known today that autism has a strong genetic component and is not considered a common consequence of severe early deprivation, researchers reported a high prevalence of autistic-like symptoms in these adopted children who had been institutionally reared and had experienced prolonged severe neglect in their early years (Hoksbergen et al. 2005; Rutter et al. 1999, 2007). Indeed, researchers attributed these autistic-like behaviors directly to the children's impoverished early environmental factors (e.g., extreme neglect, prolonged institutional care), and the provision of caring conditions for these impoverished children

led to significant developmental progress and even to the disappearance of their autistic-like deficits and delays (Rutter and Team 1998). This progress starkly contrasts with the progress trajectories of children with autism diagnoses.

Some of the adopted Romanian children showed typical features of autism as well as atypical features of autism in the preschool years. They exhibited difficulties in communication such as few reciprocal interchanges or poor conversational flow. However, their spontaneous usage of social bids and language was more flexible than that of children with autism. Adopted children who showed features of autism demonstrated inadequate social responsiveness and indiscriminate friendliness to strangers, which are both associated with reactive attachment disorder and disinhibited attachment style (Rutter et al. 2007). They also revealed repetitive and stereotyped behaviors such as intense interests and abnormal preoccupations, as well as stereotyped motor behaviors. Interestingly, as these children grew older, their typical autism-symptom manifestations became milder but were still notable. Neither the autistic symptoms' different quality nor their transient course is common in children with autism; therefore, this syndrome was termed "quasi-autistic" or "postinstitutional autistic syndrome" (Hoksbergen et al. 2005; Rutter et al. 1999, 2007).

Historical Background

Many psychological theories and clinical studies (e.g., Jean Piaget, Lev Vygotsky, John Bowlby, and René Spitz) have emphasized the importance of infants' early experiences in the first years of life for psychological development and personality characteristics. The availability of physical and social stimulation, the warm, intimate, and continuous relationship with the primary caregiver, is considered a necessary condition for infants' psychological well-being and social/emotional growth. Early studies on institutional rearing revealed that deprivation in early experiences and emotional relatedness renders a substantial impact on the intellectual, emotional, and social

development of infants and children. Institutional environments, which offer inadequate conditions for acquiring and practicing new skills, limited opportunities for reinforcement and praise, and few prospects for variation and adaptation to individual needs or differences have been associated with children's developmental delays, social/emotional unresponsiveness, and long-term psychological effects (Colvert et al. 2008; Fisher et al. 1997; Kreppner et al. 2007; Marcovitch et al. 1995; Morison et al. 1995; Rutter and Team 1998).

Due to the Romanian government's policy of outlawing birth control and abortions for women of childbearing age with fewer than five children, an estimated 100,000–300,000 children were separated from their parents who were unable to support and care for them. Even from birth, children were placed in long-term state-care institutions across Romania, which were usually impoverished and overcrowded, with a low caregiver-to-child ratio and rapid turnover in caregivers. This early deprived environment offered children little opportunity for social stimulation and personal contact in the first years of life and rendered a profound effect on children's attachment relationships and psychological development. During the early 1990s, after Western media exposure to these orphanages, large numbers of Romanian children were adopted by parents in Western countries, both for humanitarian reasons and for parents who were unable to have children of their own.

The first studies to examine the adjustment and development of Romanian adoptees, conducted shortly after adoption, reported medical problems (e.g., malnutrition, infections), eating problems, sleeping difficulties, developmental delays (e.g., in speech, language, gross and fine motor skills), stereotypical behaviors, attachment difficulties (e.g., clinging behaviors, indiscriminate approaches to strangers, overfriendliness), tantrums, hyperactivity, anxieties, and difficulties interacting with peers (Fisher et al. 1997; Marcovitch et al. 1995; Morison et al. 1995; Rutter and Team 1998). Later follow-up studies showed, importantly, that the majority of children made remarkable progress after spending time

with their adoptive families, and most of the reported difficulties tended to improve over time (Kreppner et al. 2007; Beckett et al. 2006). However, some adopted children revealed long-term effects of deprivation on psychosocial development (as will be discussed next). Most of the adoptive parents in these early studies pinpointed the importance of supportive professionals and programs like infant/child development clinics, adoption support groups, and networks of other families adopting Romanian children (Fisher et al. 1997).

Current Knowledge

Several research groups in Canada, the UK, and the Netherlands followed the development of children adopted from Romanian orphanages (Chisholm 1998; Rijk et al. 2010; Rutter et al. 2010; The St. Petersburg-USA Orphanage Research Team 2008). The English and Romanian Adoptees (ERA) study (Rutter et al. 2010) followed 165 young children adopted from profoundly deprived Romanian institutions who moved to England in the early 1990s. This group was compared to a sample of 52 nondeprived UK-born children who were adopted before the age of 6 months. So far, the children participating in this project were examined at the ages of 4, 6, 11, and 15 years, and those with autism-like symptoms were also seen at age 18–20. The children's cognitive, social, behavioral, and emotional functioning was evaluated at each time point, including specific diagnostic measures for assessing autism such as Autism Diagnostic Interview-Revised (ADI-R; Rutter et al. 2003) and Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2002).

Findings indicated a major catch-up during the preschool years; however, for some adoptees, cognitive and psychosocial difficulties were found during childhood and adolescence. The rate of deficit was significantly higher in children who stayed in deprived institutions for more than 6 months, and it persisted even more than 10 years after adoption. The Romanian adoptees' head circumference, as a measure of brain

growth, was below population norms at all ages, suggesting its possibly important role in mediating the effect of institutional deprivation on cognitive and psychosocial functioning. Interestingly, poor nutrition seemed to play a rather marginal role regarding effects on later development, whereas even very minimal language skills at the time of adoption were strongly associated with higher verbal and nonverbal IQ scores, suggesting language as some kind of a protective factor (Rutter et al. 2010).

Among these adoptees, Rutter et al. (2010) found evidence for specific outcome patterns, or a “syndrome,” associated with early deprived environment comprising quasi-autism symptoms as well as disinhibited attachment, inattention/overactivity problems, and cognitive impairments. About 10% of the Romanian adoptees who experience impoverished institutional care revealed quasi-autism symptoms compared to none of the UK adoptees. The Romanian adoptees also revealed greater deficits in executive functions and especially in theory of mind compared to the control group, both strongly associated with autism. It was suggested that these two deficits may play a significant role as mediators between institutional deprivation and quasi-autism symptoms and that institutional deprivation often led to impaired theory-of-mind abilities even when the quasi-autism symptoms were not present (Colvert et al. 2008). The longitudinal analyses of the quasi-autism patterns revealed that some of the autistic features faded over time, and in adulthood, some of the individuals with quasi-autism symptoms revealed emotional and/or behavioral disturbances such as anxieties, aggressive behaviors, as well as occurrences of outstanding skills, talents, and achievements. Furthermore, it was found that all adoptees with quasi-autism symptoms received either mental health or special education services.

The effect of early deprivation on brain structure was recently examined in a small sample of adolescents who participated in the ERA study. Using magnetic resonance imaging (MRI), significantly reduced brain volumes as well as larger relative amygdala volumes were found in the Romanian adoptee group compared

to a nonadopted matched control group, indicating possible dysfunctions in affective processing. The examination of the hippocampal and corpus callosum areas, which also play an important role in basic emotional processing and social engagement, did not reveal significant differences between these two groups, reflecting the possibility that such effects may emerge later in life (Mehta et al. 2009). Evidence for increased cortisol levels found in Romanian adoptees also supports the role of the limbic-hypothalamic-pituitary-adrenal axis in this population, reflecting the effects of prolonged stress and adversity on alterations in neuroendocrine functioning (Gunnar et al. 2001). More evidence regarding the effects of early deprivation on brain structure is coming from animal models. Severe stereotyped motor behaviors are believed to be caused by the restricted sensory environment with limited typical input. It was suggested that stereotyped motor behaviors in deprived populations serve significant functions of self-stimulating, self-soothing, or expressions of emotions such as frustration or anxiety and are associated with alterations in the cortical-basal ganglia circuitry (Bos et al. 2010).

Studies regarding gene-environment interactions have demonstrated that the association between severe deprived institutional care in the early years and the presence of long-term psychiatric problems and emotional and behavioral difficulties is mediated by genotype. More specifically, the gene coding of one of the key regulators of serotonin function in the brain – the serotonin transporter protein (5-HTT) – was detected as an important candidate to moderate the effect of adverse life stressors on emotion regulation and stress responsiveness (Kumsta et al. 2010). In addition, the dopamine transporter gene (DAT1) was also found as a possible candidate to moderate the effect of severe early deprivation and ADHD symptoms (Stevens et al. 2009). Yet, no studies have investigated brain structure or candidate genes that may moderate the associations between deprived early child-rearing environments and autistic-like symptoms.

Future Directions

The study of children who were raised in deprived institutions is considered a “natural experiment” that allows empirical scrutiny of the effects of extreme early deprivation on the development of cognitive and social/emotional functioning including the presence of autistic features. More investigations are needed to explore and identify moderating variables and factors that are responsible for the substantial heterogeneity in outcomes. For example, further genetic and biological studies using structural and functional brain imaging are needed to explore relevant genes and brain mechanisms as possible mediators for specific outcome characteristics of these adopted children, alongside analyses of variations in the quality of adoptive child-rearing environments.

[Rossetti Infant-Toddler Language Scale \(The Rossetti\)](#)

Description

The *Rossetti Infant-Toddler Language Scale* (Rossetti 2006) was designed as a comprehensive measure of the communication skills of children, birth to age 3 years. Using a combination of

observation, direct child assessment, and caregiver report, the scale is intended to tap preverbal and verbal communication and interaction skills in six domains. These include the following: Interaction-Attachment (qualities of the caregiver-infant interaction and relationship), Pragmatics (use of language in social situations), Gesture (use of gestures to communicate), Play (use of representational thought and symbolism), Language Comprehension (understanding of language), and Language Expression (production of language).

The results of the *Rossetti* are intended to reflect the child's mastery of skills in each domain and are assessed according to 3-month age intervals. The number of items for each subtest varies by age, and only those domains for which reliable and discriminating items were deemed available appear at each interval. For example, for the age interval 0–3 months, all domains are represented except Gesture (because none are expected). By contrast, only the domains of Play, Language Comprehension, and Language Expression are tapped between 33 and 36 months because only items for these domains are believed to discriminate on the basis of age.

Materials provided in the Rossetti (2006) include a score sheet, caregiver questionnaire (in English and Spanish), and Examiner's Manual. A lengthy list of additional items (e.g., spoons, balls, dolls, picture stimuli) required to administer the *Rossetti* is given in the Appendix of the Examiner's Manual.

Only professionals with knowledge of child development and communication skills are to administer the *Rossetti*. To begin the evaluation, caregivers are asked to complete the caregiver questionnaire. A parental interview guide is provided in the manual, which elaborates on the questionnaire. The practitioner may use the questionnaire and/or whatever portions of the parental interview are deemed appropriate. Completion of the caregiver questionnaire and/or interview is followed by an observation of a caregiver-child interaction during which the examiner may collect a language sample or a list of the child's vocalizations and communicative attempts. Following observation, the examiner interacts directly with the child in an attempt to elicit the remaining items

on the scale. The manual instructs the examiner to begin with the Interaction-Attachment item that corresponds to 6 months below the child's chronological age or suspected developmental level. If a behavior is neither directly observed nor elicited, the caregiver is asked to report on the child's mastery of the behavior. For example, item 17 ("Imitates stirring with a spoon") requires a cup and a spoon. To elicit the behavior, the examiner models stirring a spoon in a cup. The examiner then gives the spoon and the cup to the child with a prompt to imitate. If the child does not imitate the action, the caregiver is asked "Does your child imitate stirring a spoon in a cup?"

Items are scored as "passed" if the behavior in question is noted through observation, elicitation, or caregiver report, and each of these is given equal weight in the scoring procedure. Little guidance is provided about how to score observed behaviors which will vary as a function of the precise procedures the examiner chooses to conduct the observation. For the elicited and caregiver report scoring procedures, several guidelines, recommended questions for caregivers, and testing tips are provided for each item.

The goal of the *Rossetti* is to establish the basal and ceiling level of performance in each of the six developmental domains. Global basal and ceiling levels that provide information about the child's overall communicative skills are also available. Because the number of items differs by age, administration time varies depending on the child's chronological or expected developmental level. Testing time is also affected by variation in administration procedures (e.g., whether the caregiver fills out the questionnaire prior to the testing session or whether the examiner conducts the caregiver interview in whole, in part, or not at all).

Historical Background

The *Rossetti* was first published in 1990. Minor revisions of some items and additional information regarding scoring and interpretation were included in a later publication (Rossetti 2005). The most recent version of the measure (Rossetti 2006) is similar to the earlier ones except that it

includes a Spanish version of the caregiver interview and report questions.

The *Rossetti* was originally developed in response to the need for a measure to assess preverbal and verbal skills of children. At that time, there were a variety of measures that existed to assess motor, cognitive, and language domains. However, Rossetti (2005) noted a paucity of measures to assess the communicative skills of children under age 3 years. The focus on early language and interaction skills was justified on the grounds that communicative skills are "the single best indicator of developmental performance" (Rossetti 2005, p. 7) with noteworthy correlations with subsequent academic performance.

One feature that distinguishes the *Rossetti* from many formal measures of communicative skills is that it is a criterion-referenced measure, meaning that scores are interpreted in relation to a functional performance standard. The value of many criterion-referenced tests has been affirmed for diagnosis, assessment, and intervention. In particular, there is a common recommendation that criterion-referenced measures be used when norm-referenced interpretation of test performance are unavailable or inappropriate (McCauley 1996). There are also recent reports of the use of the *Rossetti* (Hwa-Froelich 2009) and *Rossetti* adaptations (Glennen and Masters 2002) for the evaluation of linguistically and culturally diverse children.

Psychometric Data

As Rossetti (2005) described, "only items that were considered discriminating and representative of a skill at an age were included in the scale" (p. 10). Unfortunately, no psychometric data are provided to evaluate the degree to which items *actually* discriminate between performance levels. Guidelines for the evaluation of criterion-referenced measures are offered in the Standards for Educational and Psychological Testing (American Educational Research Association [AERA], American Psychological Association [APA], and National Council of Measurement in Education [NCMI] 1999). Although the *Rossetti* appears to achieve a few of the proposed guidelines (e.g., detailed description of test user

qualification), no evidence of the measure's reliability and validity is offered in the Examiner's Manual. This is a serious shortcoming of the *Rossetti*.

Clinical Uses

The *Rossetti* was not developed to screen for, or identify children with, autism spectrum disorder (ASD). On the other hand, the evaluation of communicative skills is important in the assessment of young children with ASD who often demonstrate qualitative communicative impairments and developmental delays. In this light, the *Rossetti* may have some utility as a clinical tool in ASD as one component in an evaluation or assessment battery. As noted above, it uses a combination of observation, direct child assessment, and caregiver report, which may make it an attractive clinical choice. Because the *Rossetti* involves caregivers as major sources of information in the assessment process, the measure might also be desirable from a family-centered perspective.

Rossetti (2005) suggests that the measure can aid in early detection and intervention for children who may be at risk for developmental delay and poor academic performance. It might be used to describe the severity of a delay (i.e., mild, moderate, severe) by providing information about a child's overall communicative skills. In addition, the *Rossetti* might be used to describe a child's communicative strengths and weaknesses to guide intervention efforts and document the child's development over time. However, evidence of meaningful intervention goals and objectives that could be derived from the test is lacking at present.

As noted above, the *Rossetti* is a criterion-referenced measure and it does not yield norm-referenced scores. For this reason, it has gained some traction for use with culturally and linguistically diverse children (e.g., Hwa-Froelich 2009) who are often not represented in the normative samples of norm-referenced tests. Nevertheless, users are cautioned that no systematic empirical evidence is available to support the reliability and validity of the *Rossetti*. At present, it does not achieve industry standards (see AERA, APA, and NCMI 1999) that could justify a formal

recommendation for clinical use. As such, professionals are encouraged to consider alternative measures of early communicative skills that have been well validated (e.g., the *MacArthur Communicative Development Inventories* [CDIs]; Fenson et al. 2007). For those who choose the *Rossetti* for clinical use, careful consideration of appropriate and inappropriate interpretation of *Rossetti* scores is recommended (see Andersson 2004).

Rote Memory

Arianne Stevens and Raphael Bernier
 Psychiatry and Behavioral Sciences, University of
 Washington, Seattle, WA, USA

Synonyms

[Rote learning](#)

Definition

Rote memory is associated with recalling factual information or data. Rote memory generally entails memory for material without much reference to the meaning, emotions, or to the context to which it is associated. The major practice in rote memorization is learning by repetition or routine, without full comprehension or attention to what is being memorized. Rote memory is often prompted by external cues. Many individuals with autism spectrum disorders (ASD) have intact, if not strong, rote memory abilities. They can store vast lists of information (dinosaurs, periodic tables, bus timetables, movie scripts, etc.) for long periods of time and can recall or reproduce them accurately. However, individuals with autism typically do not use organization strategies or context to support memory. Rote memory can be viewed as an asset to individuals with ASD as they often do well on spelling bees, geography, and other contests or exams that require a large amount of information on one topic. However, rote memory can also be misleading by giving the impression that someone has higher level comprehension skills, when in fact the individual only comprehends at the factual level. The Wide Range Assessment of Memory and Learning, Second Edition (WRAML 2), is one common psychological assessment that measures memory functions and can be used across the life span.

Short Biography

Byron Rourke devoted his professional life to teaching, training, and mentoring; clinical research; and developing the field of pediatric neuropsychology. He was a cofounding editor of the *Journal of Clinical and Experimental Neuropsychology*, *The Clinical Neuropsychologist* as well as *Child Neuropsychology*. He served as president of the International Neuropsychological Society and Division 40 of the American Psychological Association. He established the clinical neuropsychology program at the University of Windsor and fostered the careers of many in the field. He was the author, coauthor, or editor of numerous books and articles on child neuropsychology and is perhaps most well known for his pivotal work on the nonverbal learning disability syndrome and model. Byron received high honors including being the recipient of a membership as a

Fellow in the Royal Society of Canada, a Gold Medal Award from the Canadian Psychological Association's Award for Distinguished Contributions to the Practice of Psychology (1994) and, more recently, investiture into the Order of Canada (2009). He is remembered as one of the preeminent child clinical neuropsychologists in the field, devoted to his students and family. He is survived by his wife Carolyne of 47 years, his sons Phil, Sean, Damon, and Bernie and nine grandchildren.

Rubella

Susan Hyman
Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital,
Rochester, NY, USA

Synonyms

3-Day measles; German measles

Definition

Rubella is a virus whose only natural host is humans. It is an RNA Rubivirus in the Togaviridae family. It is spread by droplets in the air and close contact. It infects a person through the respiratory tract and spreads to other sites in the body through the bloodstream. One-quarter to one-half of infected people are asymptomatic. Symptoms may occur 1–3 weeks after exposure. The infected person is contagious from 3 to 8 days before the typical rash appears and remains infectious for another 1–2 weeks. The rash itself starts on the face and spreads to the trunk and extremities lasting approximately 3 days. Symptoms of infection vary by age. The common symptoms experienced by children in addition to the rash are fever, chills, sore throat, headache, eye inflammation, and enlarged lymph nodes at the base of the skull (suboccipital). Adults and older children may also have joint and muscle pain, temporary problems with blood clotting (transient thrombocytopenic purpura), and itching. Rare sequelae include inflammation of the brain. Treatment is supportive. Both serology (blood measures of the antibody that the body makes to infection) and viral culture can be used to diagnose infection. Infection of a pregnant mother is much more serious than postnatal infections. Congenital infection of a fetus may result in stillbirth, fetal death, and sequelae that include deafness, visual impairment, intellectual disabilities, autism, cerebral palsy, and heart disease. Prior to the license of rubella vaccine in 1969, epidemics occurred in 6- to 9-year cycles. Between 1962 and 1965, there were 20,000 cases of congenital rubella. With high immunization rates of children in the USA, congenital rubella has all but disappeared. Rubella vaccine is combined with measles and mumps with administration recommended at 12–15 months and 4–6 years of age. Women and girls of child-bearing age are assessed for rubella susceptibility and advised regarding immunization prior to becoming pregnant. The rubella vaccine is a live attenuated vaccine and does not contain thimerosal as a preservative.

Rumination

Fred R. Volkmar
Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Merycism](#); [Rumination disorder](#)

Definition

Rumination refers to the habit of regurgitating food and chewing it again. While occasionally seen in infants who are otherwise developing normally, it is more frequent in children with developmental delays (sometimes with autism). It can also be seen in older individuals without developmental delays. The behavior can lead to various difficulties including dental problems, delays in growth, and food aspiration (inhalation of food into the lungs). Sometimes, gastroesophageal reflux contributes to the problem. Particularly if medical complications are present, interventions may be employed. Behavioral interventions can

include a range of techniques. Treatment of any associated medical problems may be appropriate.

Rumination Disorder

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Synonyms

[Merycism](#); [Rumination](#)

Short Description or Definition

Rumination refers to the habit of regurgitating food and chewing it again. While occasionally seen in infants who are otherwise developing normally, it is more frequently seen in children with developmental delays (sometimes with autism). It can also be seen in older individuals without developmental delays. Rarely, it is seen in otherwise typically developing individuals as an isolated phenomenon.

Typically food is rechewed and swallowed, but sometimes is spit out. Rumination may begin

immediately after eating/feeding or for up to an hour or so thereafter. Rumination disorder is diagnosed if the problem is persistent and a focus of treatment.

Ruminative behavior can lead to various difficulties including dental problems, delays in growth, and food aspiration (inhalation of food into the lungs). Sometimes, gastroesophageal reflux contributes to the problem. Particularly, if medical complications are present, interventions may be employed. Behavioral interventions can include a range of techniques. Treatment of any associated medical or dental problems arising from the condition may be appropriate.

Categorization

Rumination disorder has typically been defined on the basis of repeated rumination (regurgitation and rechewing of food) occurring for a period of a month or more after some time of normative functioning. The diagnosis is not made in the presence of some general medical condition that could account for its presence.

Rumination disorder is observed in several different contexts. Sometimes, it is seen in an otherwise typically developing infant or young children. More frequently is observed in association with intellectual deficiency (with or without ASD).

Epidemiology

Since much of the information on rumination is derived from case reports or small case series, available data are limited in important ways. As a practical matter, the condition is probably relatively rare. In infants (otherwise typically developing) the condition has its onset during the first year; for adults with ID (intellectual deficiency) the onset can be variable – even extending into adulthood. It is unclear if there is a gender predominance. Rumination can be associated with a number of other problems in eating/feeding.

Various factors may be involved in pathogenesis. Although typically there is an assumption that underlying GI problems are not present, this

may oversimplify a complex issue. Behavioral psychology has proposed various models that might account for rumination. It does appear that in infants, risk for rumination increased in under-stimulating environments.

Natural History, Prognostic Factors, Outcomes

The course of the conditions is highly variable. Sometimes it resolves quickly. At other times, it is persistent and then associated with various medical problems and complications, e.g., aspiration or nutritional problems may arise, GI complaints are frequent, and dental problems are common.

Clinical Expression and Pathophysiology

As noted, rumination disorder can be observed in rather different contexts – under-stimulated infants, individuals with significant cognitive delay, and sometimes in otherwise typically developing persons. The condition may be self-limited or become more chronic. Physical symptoms/associated findings can include abdominal pain (with or without constipation) as well as nausea and sometimes diarrhea and/or bloating. Dental problems are frequent if the condition persists as the acid regurgitated contributes to tooth decay.

Evaluation and Differential Diagnosis

It is important to be aware of various factors (medical and psychosocial) that might increase risk for rumination. Any associated or potentially contributing conditions should be documented. These might include medical factor such as reflux and psychosocial factors.

Treatments

A range of behavioral approaches have been used in the treatment of rumination. Early work focused on aversive methods but more recently

other approaches have been used including provision of high starch diets, chew toys, and positive behavioral techniques. Although the literature is mostly comprised of single case reports and case series, reasonably high rates of success are noted.

Russia and Autism

Alexander Sorokin
Federal Resource Center for Autism, Moscow
State University of Psychology and Education,
Moscow, Russia

Historical Background

The history of autism as a separate condition in Russia began in 1926–1927 when G. Sukhareva published two chapters which are believed to be early descriptions of the Asperger syndrome in boys and girls (Ssucharewa and Wolff 1996;

Simmonds and Sukhareva 2019). Several years later, Simson described a similar condition for preschool children (Simson 1929). These were accurate accounts of autism manifestations that the authors called schizoid psychopathy, and the clinical elaboration of autistic features was seen as formation of schizophrenic personality.

For many years, autism had been considered as a part of the schizophrenic complex of symptoms until the first classification of autism disorders was developed in a mental health research center in 1997. Its publication coincided with the decision of the Russian Ministry of Public Health to adopt the International Classification of Diseases (ICD-10). On the one hand, the national classification and ICD-10 have regularized the diagnosis of autism and other pervasive developmental disorders. On the other hand, patients with psychotic symptoms fell into three diagnostic groups: atypical childhood psychosis (F84.1) and two categories introduced in the Russian adaptation of ICD-10 (1999) – childhood psychosis (F84.02) within the group childhood autism (F84.0) and childhood schizophrenia (F20.8xx3). Especially differentiation between F84.1 and F20.8xx3 remains diagnostically problematic; thus, it is likely that many patients on the spectrum are diagnosed with schizophrenia. Moreover, autism and autism spectrum disorders are rarely diagnosed in adults and remain a child phenomenon in clinical contexts and public understanding. This will change since the Ministry of Health issued a letter that lifted age restrictions for the diagnosis of autism in 2017. A detailed account of the clinical tradition of autism understanding in Russia is given in Bashina (1999), Tiganov and Bashina (2005), and Psychiatry (2011). The situation may also change after official adoption of the ICD-11.

Since 2003, a specialized open-access Russian language journal *Autizm i narusheniya razvitiya* [Autism and Development Disorders] has been published in Moscow. It appears four times a year and covers a wide range of educational and clinical topics addressed to professionals and parents/caregivers. Along with original materials, it occasionally includes translations of articles and educational resources published abroad (<http://psyjournals.ru/en/autism/>).

Recently there have been some noticeable efforts to raise the public awareness of autism and break the understanding of autism as a solely psychiatric problem. Since 2011 the independent not-for-profit organization *Tsentr problem autisma* [“Autism Challenge” Center] has been promoting ABA intervention, organizing trainings for professionals, and starting the first pilot project of inclusive education designed for children with ASD (<http://autismchallenge.ru>). In April 2013, the Center organized the first international conference “Autism: Challenges and Solutions.” The conference has become the central annual event for autism-related topics that unite researchers, professionals, and parents in Moscow. In 2012 the first specialized foundation *Vykhod* [Way Out] (<http://outfund.ru>) was established. It focuses on promoting autism awareness, introducing services in several regions, and supporting evidence-based interventions. By 2019, the foundation organized three scientific conferences. In recent years many medical and educational conferences and congresses included a section devoted to autism research.

In the mid-2010s, the Federal Resource Center for Comprehensive Support to Children with Autism Spectrum Disorders (FRC) comprised the research and educational facility that existed over 20 years in Moscow, as a department of the Moscow State University of Psychology and Education (MSUPE, <http://autism-frc.ru/en>). Its activities are coordinated with the autism-related projects of the Ministry of Education and have been instrumental in research, outreach, and regional development.

The public awareness of autism grew considerably in recent years, especially after the success of the Russian documentary *Anton Tut Ryadom* [Anton’s Right Here] by Lyubov Arkus (2012). Every April, many cities organize events similar to the Autism Speaks *Light It Up Blue* initiative. Since 2017, a festival *Lyudi kak lyudi* [Just Like Everyone] takes place in Moscow on April 2. It was initiated by the regional charitable organization *Kontakt* [Contact] that provides legal and psychological help to families with autistic children (https://contact-autism.ru/about/who_we_are). In 2019 the

festival added numerous regional partners all over Russia (<http://2апреля.рф>).

Legal Issues, Mandates for Service

The Constitution of the Russian Federation grants the right to education for every citizen, and the Education Law of 2012 (<http://kremlin.ru/acts/bank/36698>) states that every individual with disabilities (literally, individual with restricted health abilities) should get high-quality education including early correction aimed to develop social skills. It mentions creating conditions for inclusive education. The development might accelerate after the UN Convention on the Rights of Persons with Disabilities was formally ratified in 2012. The diagnosis of autism or other developmental disorders does not automatically entitle the individuals or their families to benefits; they must apply for the disability status and its renewal.

The regional boards of psychology, medicine, and education (so-called PMPK) give recommendations about the conditions which would best serve the child, but the parents/caregivers are not legally bound to follow them and enroll the child into a school of their choice. However, the recommendations can be useful for individual provisions at schools, such as later the beginning of secondary education or special conditions during exam periods.

Overview of Current Treatments and Centers

The healthcare system sees autism as an illness that must be treated by psychiatrists. Prescription of antipsychotic and other drugs is not uncommon (Simashkova et al. 2019), often in in-clinic settings. A hospital admission can be also a necessary step when confirming the disability status. Several psychiatric hospitals have specialized units for children with ASD. In many regions medical help and rehabilitation are also provided by the Department of Labor and Social Security.

Most schools for children with disabilities have merged with general education schools that should be able to accommodate children with autism and other conditions through individualized educational plans and additional staffing, including paraprofessionals and tutors. The Ministry of Education developed and published Federal Educational Standards for Elementary Schools, four of which regulate education of children with ASD (<https://docs.edu.gov.ru/document/b903f8ab3dee1dc5e0835ee9f10b59a9/>). They differ in the number of years a child should learn in elementary school and the overall learning goals. For children who are not expected to reach the general goals even with additional years of instruction, a special individual developmental program should be developed and implemented. Inefficiency of this system in specific schools and regions can force parents/caregivers to home-school their children with ASD.

Behavioral interventions only randomly exist in official school systems, usually through support of parent organizations and foundations. Several private not-for-profit rehabilitation centers play a significant role in the regions where they exist. They are often the only institutions which provide help for individuals with autism of all ages and give access to complementary treatment approaches. Adults with ASD, who do not receive support from their families, may be institutionalized into neuropsychiatric homes, whose reform is long overdue.

Overview of Research Directions

The first publication about autism from Russia in a Western scientific journal appeared in 1993 (Lebedinskaya and Nikolskaya 1993). Most scientific and clinical books and articles are published in Russian language and because of that are not readily available for international audience. This applies to extensive literature dedicated to the differentiation of psychotic disorders, autism, and schizophrenia in children (for a recent commentary in English, see Simashkova et al. 2019). Several research groups have been publishing in international peer-reviewed

journals; they include research on chromosomal abnormalities (Vorsanova et al. 2010; Yurov et al. 2007; Zelenova et al. 2019), oxidative stress (Porokhovnik et al. 2015), and perception in autism (Stroganova et al. 2007, 2012; Sysoeva et al. 2016). Until recently comparability of experimental data with other countries was problematic because of a different diagnostic tradition. This is changing after Russian adaptations of ADOS-2 and ADI-R, which can be used for validating the clinical diagnosis, have been published. The funding of research remains insufficient: since 2012 fewer than 20 autism-related projects were supported by the Russian Foundation for Basic Research and by the Russian Science Foundation.

Overview of Training

As with other developmental disorders, only physicians and, more precisely, psychiatrists diagnose autism officially. They are trained at medical schools without pediatric specialization, unlike most doctors in other fields. A wide range of specialists provide educational and rehabilitation services. Many university departments of psychology grant degrees in special and clinical psychology. Pedagogical universities train specialists in special education and speech pathologists. No undergraduate courses are specifically dedicated to ASD, and until recently the training of special education teachers and psychologists did not address autism as a stand-alone condition. In 2014, the MSUPE introduced a 2-year master's degree program in Psychology and Education of Individuals with ASD (<http://sp.mgppu.ru/education/ras.html>). Teachers and psychologists can attend professional development courses organized by the FRC and other organizations, such as the Naked Heart Foundation (nakedheart.org), Center for Curative Pedagogics (<http://ccp.org.ru/en>), Early Intervention Institute (<http://eii.ru>), and Nash Solnechny Mir (<http://www.solnechnymir.ru/>), among others. A webinar has become a popular professional development format for professionals who cannot attend in-person trainings. The Saint Petersburg State University developed a 26-hour introductory course Autism Spectrum Disorders for

professionals and general public that is available online (<http://www.coursera.org/learn/rasstrojstva-autisticheskogo-spektra>).

Social Policy and Current Controversies

The awareness of autism grew significantly in the 2010s, and it has translated into greater acceptance. Many cultural organizations are more open and try to attract more visitors with autism with accessible programming or special provisions. For example, major art museums offer gallery and studio programs, as well as special materials for children and adults with ASD and other developmental disorders (e.g., <https://pushkinmuseum.art/museum4all/index.php?lang=en>, https://garagemca.org/en/visit/disabled_visitors/disabilities).

Main challenges to be resolved in the next years include the fire wall between providers of educational and medical services, the discrepancy between the declared inclusivity of education and available resources, as well as lack of support and inadequate possibilities for employment and education of adults with ASD.

Rutter, Michael

Fred R. Volkmar

Child Study Center, Irving B. Harris Professor of Child Psychiatry, Pediatrics and Psychology, Yale Child Study Center, School of Medicine, Yale University, New Haven, CT, USA

Name and Degrees

- Michael Rutter
- MRCS (Eng), LRCP (London), 1955 MB

- ChB (Birmingham: Distinction in Pharmacology and Therapeutics), 1955
- MRCP (London), 1958
- Academic Diploma in Psychological Medicine (London: Distinction), 1961
- MD (Birmingham: Honors), 1963
- FRCPsych, 1971
- FRCP, 1972

Major Appointments (Institution, Location, Dates)

- Professor of Child Psychiatry, Institute of Psychiatry, University of London (1973–1998)
- Honorary Consultant Psychiatrist, Joint Bethlem and Maudsley Hospitals, London (1966–)
- Honorary Director, Medical Research Council Unit in Child Psychiatry (1984–1998)
- Honorary Director, Social, Genetic, and Developmental Psychiatry Research Centre (1994–1998)
- Professor of Developmental Psychopathology, Institute of Psychiatry (1998–)

Major Honors and Awards

- Foreign Associate Member, US National Academy of Education, 1990
- Knight Baronet, 1992
- Commander of the Order of the British Empire (C.B.E.), 1985
- Fellow of the Royal Society, 1987
- Founding Fellow, Academy of Medical Sciences, 1998
- Foreign Associate Member, Institute of Medicine of the National Academy of Sciences, USA, 1988
- Honorary Fellow, British Academy, 2002
- Founding Member, Academia Europaea, 1988
- Fellow, King's College London, 1998
- Helmut Horten Award in 1997
- International Society for Autism Research, Lifetime Achievement Award, 2002
- C. Anderson Aldrich Award, American Academy of Pediatrics, 1981

- Foreign Honorary Member, American Academy of Arts and Sciences, 1989
- Adolf Meyer Award Lecturer, American Psychiatric Association, 1985
- Blanche F. Ittleson Award, American Psychiatric Association, 1991
- Honorary Degrees: University of Leiden, 1985; Catholic University, Louvain, 1990; University of Birmingham, 1990; University of Edinburgh, 1990; University of Chicago, 1991; University of Minnesota, 1993. Doctor of Science: University of Ghent, 1994; University of Jyväskylä, Finland, 1996; University of Warwick, 1999; University of East Anglia, 2000; University of North London, 2000; University of Amsterdam, 2001; Yale University, 2010; University of Oxford, 2005; University of York, 2005; University of Dublin, 2007; London University, 2008; Helsinki University, 2010

Landmark Clinical, Scientific, and Professional Contributions

The preeminent autism researcher in the world, Professor Sir Michael Rutter's contributions have spanned over four decades of seminal research. His earliest work on classification of autism helped establish the validity of the condition apart from childhood schizophrenia. His early work also illustrated the importance of structured educational interventions rather than less structured psychodynamic approaches to treatment. His early approaches to definition and his work on diagnostic nosology helped establish the recognition, and definition, of autism in the 1980 edition of the American Psychiatric Association's DSM-III. His interest in issues of classification and nosology has continued, and he was a major contributor to the revision of the current definition of autistic disorder in DSM-IV and ICD-10. Over the last decades, his interest in autism has continued and his publication record is remarkable. He has been involved in many of the most important research enterprises including, most recently, the search for genes in autism, medical correlates of

autism, and diagnosis. His work on severe deprivation in children has been path-breaking in the field.

In addition to his work in autism, other areas of interest have included resilience in relation to stress, links between development in childhood and adult, schools, psychiatric epidemiology and genetics, schools, and behavioral difficulties. With over 400 publications (books, chapters, and papers), he has had a tremendous influence on the field of child psychiatry and child development. He has taught and collaborated with many individuals who themselves have become leaders in the field.

Short Biography

Born in Lebanon to British parents, Michael Rutter lived in the USA as a child during World War II. He completed his basic training in medicine at the University of Birmingham, England, qualifying in 1955. He assumed an academic position at the University of London's Institute of Psychiatry and Maudsley Hospital in 1996 where he has since remained. He became professor of child psychiatry and head of the department of child and adolescent in 1975 (until 1995). He was knighted in 1992 and was made an honorary member of the British Academy, a fellow of the Royal Society, and founding fellow of the Academia Europaea and the Academy of Medical Sciences. The Michael Rutter Centre for Children and Adolescents at the Maudsley Hospital, London, is named in his honor.

Definition

Accidents are a leading cause of death in autism (Gillberg et al. 2010; Pickett et al. 2006; Shavelle et al. 2001). The risk for accidents in autism likely reflects the role of several factors including associated cognitive disabilities, impulsivity, and behavior problems sometimes combined with relatively good motor abilities. Unusual restricted and sensory interests may also contribute to this problem, e.g., a child who likes spinning things may try to manually explore a spinning fan. While individuals with autism can be nervous about

many new situations, at other times, they may seem driven to explore things that are intensely interesting to them.

In some ways the problem is not, of course, confined to children with autism, i.e., injuries are the leading cause of death in children and youth in the USA. For every injury that is fatal, about 200 other injuries result in emergency room visits. Some steps can be taken to insure safety for the individual both in- and outside of the home. This includes basic awareness of safety in the context of the age and level of functioning of the child. Obvious hazards should be attended to. Guns should not be in the home, and careful security should be provided for poisons and dangerous substances (including medications). Similarly, access to flammable materials, knives, and electrical cords should be limited. Within the home, careful attention should be paid to kitchen and bathroom areas and any areas that present obvious hazards (e.g., swimming pools). Given that drowning is a potential concern, children with autism should be taught to swim. Explicit teaching of safety should also occur. Various accommodations for individuals of differing levels of ability and cognitive understanding can be made. This can include use of visual support for teaching as well as special stickers that indicate that something is harmful (see Volkmar and Wiesner 2009). Parents should be aware of plants in and near the

home that may be poisonous. Both at home and school, the Poison Control Center number should be posted near the phone.

Some children present special issues that raise safety concerns. For children who mouth objects, a careful check of sources of lead-based paint should be made. Such children should not be given access to toys with small parts (i.e., that could be a choking hazard). Other children can have problems with bolting or wandering. Wandering can be presented with use of special locks, monitoring devices, and so forth. Bolting can be a problem for less cognitively able children, e.g., jumping out away from a parent on a busy street or jumping out of a car while it is in motion. Appropriate steps to insure safety should be made. Children who wander may be induced to wear a special bracelet that identifies them. Helper dogs have also been used. For children whose impulsivity is a major problem, medications and behavioral interventions can be used. In one study of bolting (Anderson et al. 2012), in over 1200 children, nearly 50% of families reported at least 1 episode of bolting in the child with ASD after age 4 years. In about a quarter of cases, the length of the absence was sufficient to cause concern. Risk for bolting increased with severity of autism.

Both at home and at school, outside areas can present special hazards. At school, the presence of other children may complicate monitoring of a child with a social disability. Accidents are probably more frequent in areas where children have less supervision and where social demands are greater, e.g., recess, gym, and cafeteria. Explicit teaching of safety concepts (including dealing with fire drills) should be part of the student's program in school. School staff should be prepared to prevent accidents and also have sufficient training in simple first aid that they can immediately respond. In some areas, e.g., where there is access to a pool or potentially dangerous materials, children should not be left without appropriate supervision. As with other aspects of teaching, a structured approach with explicit rules and routines can help teach safety concepts. This task becomes easier as children acquire language, but even for less verbal children, use of picture

schedules and visual cues can help to teach safety issues. As children get older, explicit teaching about common situations, such as crossing the street or use of simple appliances, can be included. Some computer aids are now available, and it is likely that more will be available in the future. The literature on behavioral interventions, e.g., for bolting, has also increased (Roane and DeRosa 2014; Stevenson et al. 2016).

Sainsbury, Clare

Adam Feinstein

Autism Cymru and Looking Up, London, UK

Short Biography

Born in 1974, Clare Sainsbury – a British woman with Asperger’s syndrome – studied at Oxford University in the UK. For many years, she ran an online support group for university students on the autistic spectrum. Her highly acclaimed book – *Martian in the Playground: Understanding the Schoolchild with Asperger’s Syndrome*, published in 2000 – won the TES/NASEN award for best academic book. She has spent several years working part time with children and teenagers with severe autism.

Sameness, Insistence on

Kristen Lam

UNC Neurodevelopmental Disorders Research Center, UNC-Chapel Hill, Chapel Hill, NC, USA

Definition

Insistence on sameness (IS) is a component/variant of restricted repetitive behavior, a core feature of autistic disorder. IS behaviors are characterized by extreme behavioral rigidity, where things must be “just so” and change is not tolerated. Perhaps some of the most richly detailed and clinically astute descriptions of the need for sameness found in autistic disorder can be found in Leo Kanner’s seminal paper

“Autistic Disturbances of Affective Contact” (Kanner 1943):

There is a marked limitation in the variety of his spontaneous activities. The child’s behavior is governed by an anxiously obsessive desire for the maintenance of sameness that nobody but the child may disrupt on rare occasions. Changes of routine, of furniture arrangement, of a pattern, of the order in which every day acts are carried out, can drive him to despair.

As noted above, the need for sameness in autistic disorder can manifest itself in various ways. These can include extremely rigid eating habits, insisting on taking a particular route to school or work, requiring objects to be placed a certain way, or elaborate rituals around activities of daily living. These behaviors can be excessive and may cause significant impairment to individuals with autism. Preventing or stopping such behavior is often quite difficult, as affected individuals may become anxious, agitated, or aggressive if they are interrupted. As noted by Wahlberg and Jordan (2001), people with autism seem almost incapable of adjusting their behavior to manage the many interruptions and unexpected events that can happen on a daily basis. Given the significant problems these behaviors can pose (for both the individuals with autism as well as their families), relatively little is known about their phenomenology and treatment.

Historical Background

Insistence on sameness behaviors have traditionally been subsumed under the restricted repetitive behavior (RRB) core domain of autism. In the Diagnostic and Statistical Manual of Mental Disorders – 4th Edition (DSM-IV-TR; APA 2000), criteria for RRB can be met by a person exhibiting at least one of the following: “(a) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus; (b) apparently inflexible adherence to specific, nonfunctional routines or rituals; (c) stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting or complex whole-body movements); or

(d) persistent preoccupation with parts of objects.” What becomes clear upon examination of these criteria is that they are very broad, ranging from repetitive movements of the body to more cognitively mediated symptoms such as intense interests or the need for sameness. There has been growing interest in studying the structure of RRB in autism, as identifying distinct types of behavior may help guide treatment and aid researchers in subsetting groups, as one of the major obstacles in the field has been the tremendous phenotypic variability found in the disorder.

To date, at least six studies (Bishop et al. 2006; Cuccaro et al. 2003; Lam et al. 2008; Mooney et al. 2009; Shao et al. 2003; Szatmari et al. 2006) have examined the structure of repetitive behavior in autism empirically using factor analysis of the RRB domain of the Autism Diagnostic Interview-Revised, a standardized assessment used to inform diagnosis (ADI-R, Rutter et al. 2003). An additional study examined the factor structure of RRB in more detail using the Repetitive Behavior Scale-Revised (Lam and Aman 2007). All of these studies independently verified the presence of an insistence on sameness factor in individuals with autistic disorder. This provides evidence that insistence on sameness is a distinct subtype of repetitive behavior in autism, which may aid treatment research and work examining the neurobiological and genetic underpinnings of the disorder.

Current Knowledge

Explaining Insistence on Sameness in Autistic Disorder

It is not yet understood exactly *why* individuals with autistic disorder crave sameness and loathe change. However, several theories have been offered to try to explain these sameness behaviors in autism; this has been covered comprehensively by Turner (1999). A brief summary of each of these hypotheses is below.

1. Homeostasis. This theory postulates that IS and other repetitive behaviors in autism are the result of too much stimulation from the environment, which the individual finds

aversive (Hutt and Hutt 1970). If novel situations are too arousing, then insisting on sameness in activities and the environment could help maintain homeostasis.

2. Weak central coherence. This hypothesis posits that people with autism are characterized by preferential processing of local rather than global processing of the environment (Frith and Happe 1994). This can lead to a focus on seemingly insignificant details and an inability to understand the wider context of a situation.
3. Executive dysfunction. Problems in executive functioning can lead to difficulties generating, planning, and controlling behavior. These deficits are consistent with the presence of sameness behaviors in autism; the inability to initiate novel behavior thus leads to a persistence on a restricted set of behaviors (e.g., Hughes et al. 1993).
4. Sameness behaviors as a form of compulsive behavior. Researchers have questioned whether sameness behaviors in autism are related to compulsive behaviors found in obsessive-compulsive disorder (OCD, DSM-IV; APA, 2000). Compulsions are defined as repetitive behaviors that serve to reduce anxiety or distress, rather than generate pleasure (American Psychiatric 2000). Therefore, insisting on sameness may reduce anxiety elicited by changes in the environment. This theory has also guided some medication treatment approaches in autism (described below).
5. Sensory reinforcement. Here, it is postulated that there is something intrinsically reinforcing about sameness behaviors: that the behavior is self-stimulatory (Lovaas et al. 1987).

It is important to note that it is unlikely that there is any single explanation that can account for insistence on sameness behaviors in autism. These theories are not mutually exclusive, and it is possible that individual instances may have different substrates.

Measurement of Insistence on Sameness

The Sameness Questionnaire (Prior and MacMillan 1973). This 28-item informant-based measure was developed to compare children with

autism to children with childhood schizophrenia. This questionnaire includes several items that are designed to assess the child's resistance to change (e.g., Does he insist on furniture remaining in the same place? Does he object to visiting new places?) but also includes items that assess motor stereotypies and compulsions.

The Behavior Flexibility Rating Scale (BFRS; Green et al. 2006). Intended for use in individuals with developmental disabilities, this questionnaire has 16 items that serve to identify specific situations related to a resistance to change and to rate the extent to which individuals show problems with environmental changes. Three dimensions of flexibility are assessed: flexibility toward objects, flexibility toward the environment, and flexibility toward persons.

Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al. 1999; Lam and Aman 2007). The RBS-R is an informant-completed questionnaire intended to assess the variety of RRBs observed in individuals with autism spectrum disorders. The RBS-R has 5 empirically derived subscales, one of which is called "Ritualistic/Sameness Behaviors" that has 12 items tapping insistence on sameness behaviors.

The Yale-Brown Obsessive-Compulsive Scale (Y-BOCS; Goodman et al. 1989) and *the Children's Yale-Brown Obsessive-Compulsive-Scale (CY-BOCS;* Scahill et al. 2006). Both the Y-BOCS and CY-BOCS were originally intended to assess obsessive-compulsive disorder in typically developing individuals. Due to the communication limitations in autism, usually the Compulsion section of the Y-BOCS/CY-BOCS is used. This clinician-administered rating tool does probe for some elements of sameness behavior; however, it also queries other types of RRB and provides an overall severity score for all repetitive behaviors combined.

The Childhood Routines Inventory (CRI; Evans et al. 1997). The CRI is a 23-item parental report questionnaire that assesses repetitive and perfectionistic behaviors in the context of normative development. Questions cover many aspects of insistence on sameness, such as "prefers the same household activities every day," "repeats actions over and over," and "prefers to have things done in a particular order or way."

Insistence on Sameness: Specific to Autism?

Although the need for sameness is characteristic of autistic disorder, such behavioral rigidity is also found in other populations. Repetitive, ritualistic, and "just so" behaviors are highly common among typically developing children, around the ages of 2–3 years (Gesell et al. 1974). For example, children may line up objects, have elaborate bedtime routines, and have very rigid rules around food presentation. If these demands are not met, tantrums can result; indeed, the characterization of "the terrible twos" may reflect an aspect of this normative development (Evans et al. 1997). As many as 85% of children aged 2–3 exhibit some of these "just so" behaviors, and by the age of 6 years, these behaviors begin to wane, giving way to more flexible behaviors that are necessary to negotiate the next phases of development (Evans et al. 1997).

The need for sameness is also found in other clinical populations, such as obsessive-compulsive disorder (DSM-IV, APA 1994), Prader-Willi syndrome (Wigren and Hansen 2005), and Down syndrome (Evans and Gray 2000). Research in this area is in its infancy, however. More work needs to be done to examine the specificity of sameness behaviors in autism and how (or if) they differ from other disorders in frequency, severity, and typography. Such knowledge could guide research to the neurobiological underpinnings of the disorder (Militeri et al. 2002).

Treatment

There is some debate in the literature as to whether a person with autism's desire for sameness should be accommodated (by reducing change) or be a target for treatment (by teaching the individual to cope with change) (Mesibov et al. 2005). However, for at least some individuals, the need for sameness is so extreme that it can intensify social difficulties, lead to aggression and/or anxiety, and severely limit the day-to-day activities of the entire family. In these cases, IS may be a reasonable target for intervention.

1. *Behavioral treatments.* To date, there are no well-established behavioral treatments that have focused on the reduction of IS in autism.

However, there are several established approaches in psychological literature that could be applied to reducing IS behaviors in autism, including replacement-based interventions, graduated stimulus change, and the use of visual schedules. For a review, please see Green et al. (2007). Clearly, further research is needed to fully develop and empirically validate these treatment approaches.

2. *Psychopharmacological treatments.* Because of the potential link between the compulsive behaviors found in OCD and the repetitive behaviors found in autism, selective serotonin reuptake inhibitors (SSRIs) have been of interest to researchers and practitioners alike. There have been at least seven randomized controlled trials of SSRIs in autism to date (for a review, see Williams et al. 2010). The largest, well-controlled study of citalopram in children with autism ($n = 149$) showed no reduction of repetitive behaviors in general with active treatment (King et al. 2009). At this point, there is not a great deal of empirical support for the use of SSRIs to treat repetitive behavior in autism. However, in these studies, repetitive behaviors were measured more generally; it is unknown whether extreme IS behaviors in particular would be more responsive to treatment with an SSRI. More research in this area may be warranted.

Future Directions

As stated previously, one of the largest obstacles in the study of autistic disorder is the extreme variability and heterogeneity in the phenotype. One promising line of research is to use insistence on sameness to subset groups. Although insistence on sameness is characteristic of autistic disorder, not *all* people with autism display this class of behavior. Identifying individuals with high levels of IS may be a way to identify groups of people with autistic disorder that are more behaviorally homogeneous, which would be of tremendous use to workers in the field who are trying to delineate the neurobiological and genetic causes of autism.

Although research in this area is in its infancy, there is growing evidence that insistence on sameness in autism may have, at least in part, a genetic

basis. Several groups have looked at sibling pairs with autism to see how insistence on sameness aggregates in families (Cuccaro et al. 2003; Lam et al. 2008; Shao et al. 2003; Szatmari et al. 2006). Three of these studies (Shao et al. 2003; Szatmari et al. 2006; Lam et al. 2008) provided evidence that insistence on sameness behaviors are familial (whereas another forms of repetitive behaviors, Repetitive Motor Behaviors, are not). Further evidence for a genetic basis for IS behaviors is provided by recent study of the relationship between sameness behaviors in individuals with autism and obsessive-compulsive symptoms in their parents (Abramson et al. 2005). Briefly, they found that insistence on sameness was positively correlated with obsessive-compulsive behaviors in parents. Further, when individuals with autism were grouped on the basis of parental Y-BOCS scores (clinically significant versus nonclinically significant), individuals whose parents had clinically significant Y-BOCS scores had higher ADI-R insistence on sameness factor scores.

It is recognized that although autism is a strongly genetic disorder, its phenotypic presentation is so complex that the identification of candidate genes or other etiological mechanisms is unbelievably complex. These studies provide preliminary data that subsetting groups of individuals with autism by severity of insistence on sameness may be a useful way to reveal phenotypically and potentially etiologically distinct subgroups of individuals with autism. More research in this area is needed.

Savant Skills (in Autism)

Darold A. Treffert

St. Agnes Hospital, Fond du Lac, WI, USA

Definition

Savant syndrome is a rare but remarkable condition in which persons with developmental disabilities, including autism, have some spectacular, exceptional, and unexpected abilities (“islands of genius”) that stand in marked, jarring juxtaposition to overall limitations. These special abilities are generally music, art, calendar calculating, lightning calculating, or mechanical visual-spatial skills. Whatever the special ability, it is always coupled with massive memory which is exceedingly deep, but limited within very narrow confines.

Savant syndrome occurs in approximately one in ten persons with autistic disorder, ranging in ability from “splinter skills” to “talented” to “prodigious.” That latter term is a high threshold category in which, in absence of a disability, the person would be classified as a prodigy or genius; there are probably fewer than 100 known, living prodigious savants in that extremely high-level performance category. Savant syndrome can be congenital (present from birth) or acquired (a neurotypical person in whom unexpected savant abilities emerge following head injury, stroke, dementia, or other CNS disease).

Savant syndrome is not a disease or disorder by itself. The special abilities seen in the savant are always grafted on to some underlying disability, including autistic disorder.

Theories to Explain Savant Syndrome

There is no single theory which can explain all cases of savant syndrome. Neuropsychologists have concentrated on “weak central coherence,” “mind blindness,” “executive dysfunction,” and “hypersystemizing” as core defects in both autism and savant syndrome. These ideas are discussed at length in the 2010 book *Autism and*

Talent by Happe and Frith which addresses the question of why savant syndrome is overrepresented in autistic disorders compared to other developmental disabilities. Rimland (1964) and Treffert (2010) postulate that in the savant, there is a process of “recruitment,” “rewiring,” and “release” of available and still intact brain capacity as a compensatory mechanism for damage to other brain areas (most often left hemisphere) and damage to the higher level semantic memory circuits which produces a reliance on lower level, habit or procedural memory circuits. This produces the typical clinical picture of right brain skills coupled with “automatic” memory seen most often in the savant. Casanova and Trippe (2010) propose that differences in connectivity, favoring short-range connections compared to long-range connections in minicolumns of the brain, are responsible both for autism itself as well as the novel abilities of savants. Powell (2006) and others have been exploring how “quantum mechanics” and the mechanism of “entanglement” might account for savant abilities including even the extrasensory perception or “psi” capacities in some savants. This theory suggests that suppression of the “dominance” of one area of the brain permits both the release of non-dominant skills and the “without reckoning” memory of savants. The brain area release and substitution phenomenon has been called “paradoxical functional facilitation” and is applicable in both congenital and acquired savants (Kapur 1996).

Historical Background

The first account of savant syndrome is a scientific paper that appeared in the German psychology journal *Gnothi Sauton* in 1873, describing lightning calculator with an extraordinary memory (Moritz 1783). Rush (1789) reported the case of Thomas Fuller, a lightning calculator “who could comprehend scarcely anything, either theoretical or practical, more complex than counting.” But the word “savant” did not appear until 1887 when Down described eleven patients with “special faculties” among the hundreds of patients with severe

cognitive disabilities he had seen during his career at Earlswood Asylum in London. These skills included art, music, mathematics, precise time-keeping, and memory. One boy had memorized “The Rise and Fall of the Roman Empire” and could recite it backward or forward. Down named this condition “idiot savant” since at that time “idiot” was an accepted scientific term for IQ below 25. He combined that with the term “savant” derived from the French word *savoir* meaning “learned person.” It is not clear how many of Down’s patients were autistic, as distinct from mental retardation, but in that same article Down described what he called “developmental retardation” as separate from “congenital” and “accidental” retardation. In so doing, it is clear his “developmental retardation” category would include what is now classified as early-onset and late-onset autistic disorder (Treffert 2006).

In his 1914 *Mental Deficiency (Amentia)* textbook, Tredgold devoted an entire chapter to the “idiot savant” with a succinct, colorful, and capturing description of the idiot savant. That term endured until 1988 when Treffert suggested “savant syndrome” be substituted as the name for this remarkable condition because of the negative connotation of “idiot” and because not all persons with savant syndrome have low IQ. Then in 1988, the popular, award-winning movie *Rain Man* made “autistic savant” household words. That was an extremely useful public education tool but with the caveat that not all persons with autism are savants and not all savants are autistic.

Current Knowledge

The Condition Is Rare but One in Ten Autistic Persons Show Some Savant Skills

In Rimland’s (1978) survey of 5,600 children with autism, 531 (9.8%) were reported by parents to have special abilities, and a 10% incidence of savant syndrome in autistic disorder has become the generally accepted figure in autistic disorder. However, Hermelin (2001) estimated the incidence to be as low as “one or two in 200.” Bolte and Poustka (2004) identified savant skills in 13% of 243 individuals with autism based on at

least one special skill as assessed on the Autism Diagnostic Interview-Revised (ADI-R). Howlin et al. (2010) reported that in a sample of 137 persons with autism involved in long-term follow-up, 28.5% of individuals showed some savant skills based on either cognitive testing or parental reports. That number is probably higher than in other studies because the presence of savant skills, in some cases, was based solely on cognitive scores, particularly block design, on formal IQ testing.

The generally accepted figure for prevalence of savant skills in autistic disorder remains at about one in ten (10%). That figure may be adjusted upward somewhat as larger series of such cases are assembled.

But savant syndrome is not limited just to autistic disorder. In a survey of an institutionalized population with a diagnosis of mental retardation, Hill (1977) reported the incidence of savant syndrome was 1:2,000 (.06%). A more recent survey of 583 facilities found a prevalence rate of 1.4 per 1,000 (Saloviita et al. 2000). Whatever the exact figures, mental retardation and other forms of developmental disability are more common than autistic disorder, so a reasonable estimate is that approximately 50% of persons with savant syndrome have autism as the underlying disorder and the other 50% have other forms of developmental disability, mental retardation, or other CNS injury or disease as the underlying disorder. Thus, not all autistic persons have savant syndrome, and not all persons with savant syndrome have autistic disorder.

Interestingly, in Kanner’s (1971) follow-up of his original 11 cases, 6 had outstanding savant skills in music or memory. In Miller’s (1998) report on 45 individuals with savant abilities, 22 had autism or symptoms highly suggestive of that disorder.

Savant Skills Typically Occur in Particular Categories of Abilities

Considering all the skills in the human repertoire, it is interesting that savant skills narrow to five general categories: *music, art, calendar calculating, lightning (rapid) calculation, and mechanical and/or spatial skills* such as measuring distances

with precise accuracy, the ability to construct complex models or structures, map-making, or direction finding. These special skills tend to be those associated with right hemisphere function. Other skills are also reported from time to time such as polyglot (language acquisition); unusual sensory discrimination in smell, touch, or vision including synesthesia; perfect appreciation of passing time without benefit of a clock; and outstanding knowledge in specific fields such as neuropsychology, statistics, or navigation.

Generally, a single skill exists, but in some instances several skills exist simultaneously. Whatever the special skill, it is always accompanied by prodigious memory. Some observers rank memory as a separate special skill. However, prodigious memory within the area of the special skill cuts across all the special ability areas as a shared, integral part of the syndrome itself.

There Is a Spectrum of Savant Skills

The most common form of savant skills are “*splinter skills*,” which include obsessive preoccupation with, and memorization of, music and sports trivia, license plate numbers, maps, historical facts, or obscure items such as vacuum cleaner sounds, for example. *Talented savants* are those whose special skills are more highly honed and are very conspicuous when viewed in contrast to overall limitations. *Prodigious savants* are those persons whose skills are at such a spectacular level that if no disability was present, they would be classified as prodigy or genius (Treffert 1988).

The Special Skills Are Always Accompanied by Massive Memory

Whatever the special abilities, a remarkable memory of a unique and uniform type yields the condition together. Terms such as automatic, mechanical, concrete, and habit-like have been applied to this extraordinary memory. Down (1887) used the term “verbal adhesion”; Critchley (1979) used the term “memory without reckoning,” and Tredgold (1914) used the term “automatic.” Such unconscious memory suggests what Mishkin et al. (1984) referred to as nonconscious “habit” formation rather than a “semantic”

memory system. They proposed two different types of memory: a higher level corticolimbic circuit for semantic memory and a lower level corticostriatal circuit for the more primitive habit memory, which is sometimes referred to as procedural or implicit memory. Savant memory is characteristically very deep, but exceedingly narrow within the confines of the accompanying special skill.

Males Outnumber Females in Both Autism and Savant Syndrome

Males outnumber females in savant syndrome by an approximate of 6:1 ratio compared to an approximate of 4:1 ratio in autistic disorder. In explaining that finding, Geschwind and Galaburda (1987) point out in their work on cerebral lateralization that the left hemisphere normally completes its development later than the right hemisphere and is thus subjected to prenatal influences, some of which can be detrimental, for a longer period of time. In the male fetus particularly, circulating testosterone, which can reach very high levels, can slow growth and impair neuronal function in the more vulnerably exposed left hemisphere, with actual enlargement and shift of dominance favoring skills associated with the right hemisphere. A “pathology of superiority” was postulated, with a compensatory growth in the right brain as a result of impaired development or actual injury to the left brain.

This finding explains why the savant skills described above tend to be “right brain” abilities. It may account as well for the high male/female ratio in other disorders, including autism itself, since left hemisphere dysfunction is often seen in autism (Rimland 1964; Treffert 2010). Other conditions, such as dyslexia, delayed speech, and stuttering, also have a high male predominance in incidence, which may be a manifestation of the same left hemisphere growth interference in the prenatal period described above.

Intelligence and Savant Skills

When Down coined the term “idiot savant,” it was immediately linked with mental retardation since at that time “idiot” referred to an IQ below 25. As it turns out, that was not only a regrettable term for

present day usage, but it was also in error since almost all reported cases have occurred in persons with an IQ above 40. That early association with mental retardation has led to the erroneous impression that savant syndrome is always associated with cognitive impairment. That is not the case. *Low IQ is not a requisite for savant syndrome.*

IQ levels in savant syndrome can range from below 40, which is quite rare, to as high as 140. The majority of savants have IQ levels between 40 and 70, but as many as 25% have IQ scores above 70. Bolte and Poustka (2004), for example, compared performance of 33 savant and 26 nonsavant autistic subjects on the Wechsler Adult Intelligence Scale-Revised (WAIS-R). Full-scale IQ scores for the savants ranged from 38 to 128, with a mean of 83.3; the nonsavant autistic control group IQ levels were somewhat lower (71.4) but that was not statistically significant. Miller (1998), in a review of studies where detailed IQ information was available, found that the mean overall IQ/IQ estimate for savants with autism was 71 (range 40–99) with the mean verbal IQ of 77 (range 52–114) and mean nonverbal IQ of 75 (range 47–92). Howlin et al. (2010) found, in their 10-year follow-up on 137 autistic savants, that nonverbal ability, using a variety of tests appropriate to each individual, gave a mean performance level of 69.9 (range 28–135). Verbal ability scores in that group showed a mean verbal IQ/or ratio IQ estimate (based on any test) of 52.9 (range 7–134).

Thus, although savant syndrome *can* occur in persons with autism with very low IQ scores, in the majority of cases IQ falls within the mild learning disability range.

Some autistic savants do have IQ levels in the superior range, and wide scatter on intelligence testing is a consistent characteristic of this group. Because of the wide scatter on such testing, some investigators have concluded that savant syndrome argues for “multiple intelligence” theory against “general intelligence” and the validity of the g factor (Treffert 2010). Whatever the case, while some savants do have IQ scores below 70, having an IQ score above 70 does not “disqualify” someone from having savant syndrome.

“Treatment” and “Training the Talent”

Savant syndrome is a combination of special skills grafted on to some underlying disability such as autism. Any formal “treatment” therefore would be directed at the underlying disability. With respect to the special skills, appropriate intervention is called “training the talent.”

In 1930, Phillips framed the question of dealing with special skills this way: “The problem of treatment comes next. ...is it better to eliminate the defects or train the talent?” Experience since that time shows that question need not be either/or. Instead, by “training the talent,” one can actually help ameliorate the “defect.” Supporting and nurturing whatever the special skill – music, art, and math – leads eventually to improved language, social, and daily living skills *without trade-off or loss of those special skills* as progress continues in other areas of functioning and learning. The special skills are a way of engaging the savant. They are not frivolous or interfering. They are a form of expression and can be a “conduit toward normalization,” with the eventual goal of channeling those abilities more usefully.

Clark (2001) developed a savant skill curriculum using a number of successful strategies currently employed in the education of gifted children (enrichment, acceleration, and mentorship) and autism education (visual supports and social stories) in an attempt to channel and apply, usefully, the often nonfunctional obsessive savant and splinter skills of a group of students with autism. This special curriculum did prove highly successful in the functional application of savant skills and an overall reduction in the level of autistic behaviors in many subjects. Improvements in behavior, social skills, and academic self-sufficiency occurred, along with better communication skills in some subjects. These strategies are woven into a number of successful approaches now in various autism treatment centers and classrooms.

Simultaneously, some specialized schools are developing, such as Soundscape Centre in England which is the only specialized educational facility in the world uniquely dedicated to the needs and potential of persons with sight loss

and special musical abilities, including musical savants. Some savants with special graphic abilities have now graduated from prestigious art schools, and some with special musical abilities have likewise graduated from equally prestigious music schools. There are also a number of savants with a Ph.D. degree in mathematics or other fields.

Grandin and Duffy's book – *Developing Talents: Careers for Individuals with Asperger Syndrome and High-Functioning Autism* (2005) – is an excellent, practical resource which outlines methods for helping children “develop their natural talents” using “drawing, writing, building models, programming computers,” and similar skills to help in the search for eventual work experience.

The Case of Nadia and the “Dreaded Trade-off” Versus Progression of Skills

In 1978, Selfe reported the case of Nadia who lost her special art skills when exposed to traditional schooling. This raised the question whether there might be a “dreaded trade-off” of special skills for acquisition of better language, social, and daily living skills. Experience has shown this to be not the case, and Nadia's experience is the exception rather than the rule.

Rather, based on following certain savants over a number of years, a pattern of progression of savant skills emerges first with *replication*, then *improvisation*, and finally, in some cases, the capacity to be *creative*. A fuller description of this pattern of progress in a number of savants can be found in Treffert's, 2010 *Islands of Genius: The Bountiful Mind of the Autistic, Acquired and Sudden Savant* book or his chapter on savant syndrome in *Autism and Talent* (Happé and Frith 2010).

Family History and Savant Syndrome

The role of family history in savant syndrome is an unsettled one. Two studies, one with 25 savants and another with 51 subjects, showed relatives with special skills in *some*, but not all, cases (Duckett 1976; Young 1995). Young traveled to a number of countries and met with 51 savants and

their families. There was a family history of similar skills in some, but not all, cases, but even in the absence of a history of a specific skill, there was a familial predisposition toward high achievement.

Might there be a gene for savant syndrome? Here, results are also mixed. Nurmi et al. (2003), using parental reports on special skills, compared 21 multiplex autism families (multiple affected members, mainly affected sibling pairs and their parents) which he identified as “savant skills positive” with 74 similar families that he identified as “savant skills negative.” Results showed “the subset of 21 savant skills positive families yielded significantly increased evidence for linkage to 15q11-q13.” The 73 families in which the individuals with autism had few or no savant skills showed no evidence of such linkage. Ma et al. (2005) attempted to replicate those findings using the savant skill factor (SFF) from the Autism Diagnostic Interview-Revised (ADI-R) instead of parental reports. Their results “failed to demonstrate linkage to 15q-11-q13” in their sample. But the differing definitions for savants in these two studies make for a difficult comparison.

The exploration of family history in savant syndrome, based on experience thus far, suggests that “family history” needs to extend beyond first-degree relatives to uncles, aunts, and cousins, for example, and beyond the present generation to prior generations in the family. Only with that more extensive and careful exploration will the contribution of family history to savant syndrome become more clear.

Future Directions

There has been more progress toward better understanding savant syndrome in the past 25 years than in the prior 100 since Down's first description of this extraordinary condition in 1887. Many unanswered questions still remain but interest in exploring those is accelerating, particularly with the rapid emergence of newer technologies that allow the study of brain

function, not just brain *structure*. Savant syndrome provides a unique window into the brain, using those new techniques, to learn more talent, memory, and creativity itself, not only in savants but in everyone else as well. Future direction of research to better understand the savant and services to better help him or her to reach their full potential will include what follows.

New Technologies

The brain sits well protected in the rigid box surrounding it. It cannot be “scoped” like other organs and biopsies are problematical. Therefore, various imaging techniques are the least intrusive way of studying brain structure and organization. CT and MRI scans permit high-resolution images of brain architecture, including deep structures. Even more illuminating though are functional studies such as PET and SPECT. Those require isotopes however, so functional MRI (fMRI) is more often used to look at the brain at work. And it is study of brain function that will ultimately provide keys to better understanding not just savant syndrome but autism itself.

Some theorize that autism, and savant syndrome, is a result of abnormal “connectivity” in the brain. Diffusion tensor imaging (DTI) measures water flow in the complex neuronal network, and diffusion tensor tracing (DTT) traces those actual connections between the hemispheres, within the hemispheres, and between the upper and lower brain structures, projecting tracings of the actual fibers and the pathways that connect those fiber tracts. Casanova and Trippe (2010) speculate that minicolumn organization (or disorganization) may be vital in autism itself, and Mottran et al. (2006) and colleagues extend changes in synaptic plasticity to account for some unusual synaptic connectivity in savant syndrome. Studies of such connectivity patterns are also underway.

One of the problems with studying savant syndrome with these technologies is that it requires virtual immobilization in the MRI and similar machines. It is impossible of course to play a piano, or sculpt, in an MRI machine. So in order

to truly view the brain while the savant is “at work” with their special skill, methods need to be devised to allow brain function studies with less immobilization. Near-infrared spectroscopy (NIRS) measures hemoglobin flow using a scalp cap and does not require the individual to be immobile and will be applied in such studies. Also new magnetoencephalography technology provides a great deal of information beyond traditional EEG in terms of sensitivity and magnification, and it can provide extremely detailed information about the electrical activity in both surface and deep areas in the autistic and savant brain.

A Savant Syndrome Registry and Broad-Based, Controlled Studies

The relative rarity of savant syndrome, contrasted with the attention-getting extraordinary nature of some abilities, has led to largely anecdotal reporting of cases through the years. The lack of a standardized definition of “savant syndrome,” the absence of uniform neuropsychological testing of savants, and the lack of quantification of savant skills into distinct categories has hampered research efforts with large sample, control groups. To that end, a *worldwide savant syndrome registry* has been recently organized by Treffert and Rebedew collecting cases largely from the savant syndrome web site at www.savantsyndrome.com along with professional journal reports, personal correspondence, and media descriptions. To date, 309 cases of savant syndrome from 33 countries have been entered into that registry. Those cases have been categorized by ability, disability (formal diagnosis) age, gender, family history, medical history, congenital or acquired type, geographic location, and a number of other variables. From that analysis, now underway, there can be determination, on a large sample basis, of the distribution of autism versus other diagnoses as the underlying disability, the frequency of various abilities, a breakdown of congenital cases versus acquired cases, gender distribution of savant skills, age of savants, family history, medical history, educational level, vocational and

socioeconomic status, and a variety of other parameters. Cases will be added to that registry as they are discovered and reported. A second phase of that “registry” will consist of gathering information from an even more detailed questionnaire completed by those savants, families, and caregivers willing to do so.

Having savants registered by geographic location should help those researchers hoping to find willing subjects in their particular countries to participate in these larger case studies including control groups.

Exploring the Interface Between Prodigy, Genius, and Savant Syndrome and Other Quandaries

As more savant cases come to attention, both congenital and acquired, the interface between prodigy, genius, and savant syndrome becomes a natural area for exploration. These conditions likewise provide a fertile field for investigation regarding the nature of talent and the role of “innate” versus “learned” abilities, the age old nature versus nurture argument. They also raise the question of “multiple” intelligences versus a “general” intelligence, or “g” factor. Savants, whether congenital or acquired, seem to “know things they never learned,” which gives entry to the area of genetic or ancestral memory for exploration as well. Finally, savant syndrome, both congenital and acquired, provides a striking confirmation of brain plasticity and is a natural workshop to explore those mechanisms as well. Research into these areas is already underway, and more will follow.

Development of Methods of “Training the Talent” and Resources to Use Those Special Skills

A better understanding of, and appreciation for, savant skills has taken them out of the “Gee whiz, look at that” category and cast them into a vigorous treatment – “training the talent” – effort with the hope those special abilities can be used vocationally in many cases fostering increasing independence and community acceptance. Studies are

underway, and will increase in the future, as to what are the best methods to use in education efforts: special classrooms, regular classrooms, or hybrid approaches. Already, some programs have successfully placed savant and neurotypical “gifted and talented” students together in combined programs. Private schools specifically designed for, and dedicated to elementary, middle school and high school students with savant syndrome and high-functioning autism have likewise emerged. Those provide particular populations for research on program effectiveness and outcome.

But while there has been the development of an increasingly rich network of educational services for K-12 students with savant syndrome, autism, and Asperger’s, until recently those students, now adults, have faced a very barren landscape of similar services for the over-18 age group. But that is changing for the better, and there is a solid effort underway to incorporate more adult savants, with their special talents, into the regular workforce. Grandin and Duffy (2005) have provided a good blueprint for developing talents as a pathway to careers that utilize the unique skills of the savant. There are now employment agencies in several countries that successfully specialize just in the matching of individuals with Asperger’s with willing employers. The years ahead will see more and more such efforts as the network of services for the over-18-year-old autism and savant populations expands to provide a comparable network of services available to them during their regular school years. A very comprehensive Transition Tool Kit is available from *Autism Speaks* either as a printed version or downloaded at the *Autism Speaks* web site (request Autism Speaks Transition Tool Kit). It fills a need for practical information for persons with savant syndrome, and their families, in making the transition to adulthood.

A Challenge to the Capabilities of All of Us

Until savant syndrome can be fully understood and explained, there can be no explanation and understanding of the full intricacy and capacity of the human brain. For no model of brain function,

including memory, will be complete until it can fully incorporate and elucidate how it is possible to have such a jarring juxtaposition of ability and disability within the same individual. While that question has intrigued all the researchers approaching it, this past century and a quarter since first described by Down, newer technologies now make it possible to more clearly unravel this remarkable condition, with all the implications it has for better understanding not just the savant but in better understanding brain function in everyone in terms of talent, skills, learning, memory, and creativity itself.

But there is more to savant syndrome than just neurons, circuits, and the brain's marvelous intricacy. Future research findings will surely be of great *scientific* interest. But there are many lessons to be learned as well of *human* interest from these remarkable people and their equally remarkable families, caregivers, teachers, and therapists that surround them. These people that care *about* the savant, as they care lovingly *for* them, provide valuable examples of the power of unconditional positive regard, support, encouragement, patience, and optimism that benefit anyone “differently abled” (as it is sometime called) with savant syndrome and autism. The investigation of both the scientific interest of the savant, as well as the human interest involved, can provide valuable and unique insights into actualizing and maximizing human potential in whomever, and in whatever quantity, it exists within all persons.

condition is rare, but because of the striking skills that some savants have, it has captured the attention of the general public and researchers. Savant talents vary from exceptional mathematical abilities, to prodigious musical skills, to extraordinary artistic talent.

Historical Background

The first documented case of savant syndrome appeared in the literature in the late eighteenth century. In 1887, Dr. J. Langdon Down, well-known for his identification of Down's syndrome, described savant syndrome as its own condition. In his lectures he described ten different cases that had been identified (Treffert 2014). Until several decades ago, savants were called “idiot savants.” This title is not only jarring to the modern ear, but entirely inaccurate. “Idiot” was formerly used to describe those with an IQ under 25. However, almost all individuals with savant syndrome have IQs above 40 (Treffert 2009). In the late twentieth century, the condition was renamed savant syndrome (Rimland and Hill 1984). In 1980, autism was first listed in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) under infantile autism (Camulli and Goh 2018). In 2013, the diagnosis in the DSM was generalized to autism spectrum disorder. Although some symptoms of savant syndrome are included in the DSM-V, it is not categorized as a distinct diagnosis.

Various definitions of savant syndrome have been proposed since it was first identified in 1887. Due to immense variation in both the special skills and underlying developmental disabilities associated with it, characterizations of the condition have focused mainly on the juxtaposition between the talent and the underlying impairments (Bennett and Heaton 2017).

Savant Syndrome

Meital Gewirtz

Yale University, New Haven, CT, USA

Definition

Savant syndrome is a disorder characterized by a niche area of immense talent that contrasts with a general intellectual impairment. Many people with savant syndrome also have autism. The

Current Knowledge and Research

While savant syndrome is more common in individuals with autism than in the general population, it is still extraordinarily rare. According to

the Centers for Disease Control and Prevention, between 1% and 2% of the global population has autism spectrum disorder (Baio et al. 2018). Of that number, about 10% of individuals with autism have some form of savant syndrome (Camulli and Goh 2018). Due to the rareness of the disorder, research into its mechanisms is sparse. The research that does exist relies primarily on case studies rather than on experimental studies. This presents challenges in drawing significant conclusions about the basis of the disorder.

It is a common misconception that savants are only found among those with autism. Only 50% of people with savant syndrome have a diagnosis of autism. The other 50% have some other underlying developmental disability or CNS disorder, including Prader-Willi syndrome or Smith-Magenis syndrome (Corrigan et al. 2012). Savant syndrome appears far more frequently in males than in females. Although this is true of autism as well, the imbalance is greater in savant syndrome. Whereas autism is four times more likely to occur in males than in females, savant syndrome is six times more likely to occur in males (Treffert 2009). Autistic savants and autistic non-savants are similar in that they both show deficits in communication abilities and other social skills (Bennett and Heaton 2017). There are also no significant differences in IQ in verbal, performance, or processing speed; however, savants tend to score more highly on working memory.

The core symptoms of savant syndrome include a developmental disability, a specific skill, and interest in that specific area (Camulli and Goh 2018). Researchers and clinicians describe savants as falling on a spectrum, depending on the nature and level of accomplishment within their skillset. Talented savants typically have a narrowed skillset in music, art, or some other area that contrasts with their disability (Treffert 2009; Camulli and Goh 2018). At the extreme end of the spectrum, prodigious savants have abilities that would be considered extraordinary by any measure. This form of savant syndrome is extremely rare. It has been estimated that there are only about 25 prodigious savants in the world presently (Camulli and Goh 2018).

Most commonly, savants' skills arise or are identified at a very young age. Nevertheless, there have been a number of documented cases of savant syndrome being acquired at a later age, typically following a brain injury (Lythgoe et al. 2005; Treffert 2009). With the exception of one report, in which the savant's skills deteriorated over time, savants are able to improve their skills through training and practice (Hou et al. 2000; Treffert 2009).

Among the unusual range of talents of savants, several special abilities are more commonly seen. The most frequent is calendar calculations, in which an individual can rapidly determine a specific day of the week that a date fell on, sometimes going back centuries, and often correctly accounting for leap years (Brink 1980). While a typical individual could learn this skill, it comes more effortlessly to a subset of people with savant syndrome. Other documented abilities include artistic expression, mechanical abilities, or musical skills (Brink 1980; Corrigan et al. 2012). Perfect pitch, while rare in the general population, is far more common among savants. Additionally, mastering several languages (Smith et al. 1993) has been documented. People with savant syndrome tend to have a very narrow range of skills, although in a few cases, individuals have multiple talents (Treffert 2009). Accompanying their remarkable talent, people with savant syndrome often have exceptional memory.

Some researchers have described people with savant syndrome as having exceptional memory and the ability to learn within their skillset quickly, but lacking the creativity to improvise or compose new music or art. This, however, is untrue. There have been a number of documented cases of savants showing creativity in their area of expertise. In one case, a man named Leslie who was very skilled musically began by reproducing songs on the piano. This in itself took a high level of skill, as he could replicate very advanced and long pieces after hearing them only once. After further developing his talent, he could later improvise or compose his own pieces (Treffert 2009). This demonstrates the complicated nature of the abilities of those with savant syndrome and the uniqueness of each case.

Some characteristic physical phenotypes are more likely to manifest in individuals with savant syndrome. For example, visual impairment is more common in savants with significant musical skills (Treffert 2014). There have also been several cases of savants with epilepsy or seizure disorders.

The most carefully documented cases are of prodigious savants, despite their rarity. The first reported case in 1783 described a man named Jedediah Buxton as a “lightning calculator” because of his exceptional mathematical abilities (Treffert 1988). Several artistic savants have been described, including Gottfried Mind, born in 1768, who was exceptionally skilled at drawing cats from memory (Hou et al. 2000). Kiyoshi Yamashita, born in Japan in 1922, was called the “van Gogh of Japan” (Hou et al. 2000). Stephen Wiltshire is a modern example of an artistic savant. He became well-known because of his accuracy in drawing cities after seeing them only once (Höfer and Röckenhaus 2015).

Musical savants are also well documented. Blind Tom, a former slave, became well-known in the nineteenth century for his remarkable piano playing abilities. His extraordinary memory allowed him to replicate a song perfectly after only hearing it once. Derek Paravicini, a modern-day musical savant, is also blind and autistic. Similar to Blind Tom, Derek can play a song flawlessly after hearing it once (Moss 2007). He can also improvise and create music on the spot. Derek’s musical genius would be remarkable in a typically developing person. However, Derek is particularly notable in that he has significant cognitive disabilities, in addition to being blind (Moss, 2007). When he first played the piano at the age of 3, he did not realize that the piano is supposed to be played using one’s fingers. Until he was formally taught, he played with his elbows or the backs of his hands (Moss 2007). Now, he displays his talents widely and is celebrated for them.

Other prodigious savants are renowned for their great memory. Perhaps the most well-known savant is the fictional character, Raymond Babbitt, from the movie *Rain Man*. The character was based on a real individual named Laurence Kim Peek, who has memorized thousands of

books and has an excellent memory for geography. He is able to read very quickly, as he reads one page with his left eye and one with his right eye and has no corpus callosum (Brogaard 2012).

While many reports of savant syndrome describe cases in which the individual was born with notable skills or developed talents at a young age, several cases have been described of “acquired” savant syndrome. In acquired savant syndrome, significant talents emerge after a traumatic brain injury. After a gunshot wound to the head, Mr. Z was reported to have lost the ability to speak, read, or write. However, he gained significant skills in mechanics, geography, and art (Brink 1980). Researchers theorized that the injury to his left hemisphere led to further development of the right hemisphere, which resulted in the emergence of skills in these areas.

No single cognitive or biological mechanism has been proposed that can account for all cases of savant syndrome. One historical explanation was that savants’ exceptional skills were the result of a tendency to practice them intently or even excessively, due to more rigid behavioral patterns. However, several studies have shown this not to be the case. Although savants are more obsessive than neurotypical control groups, there is no difference in obsessive behavior between savants and non-savants with autism (Bennett and Heaton 2017). Given that the skills of savants are remarkable when compared to typical children who practice seriously, a purely behavioral explanation of this kind is unlikely. Rather, the disorder is ultimately more likely to be explained in terms of neuroanatomical abnormalities and/or dysfunctional neurobiological mechanisms.

There have been several case studies in which brain structure has been studied in savant syndrome. A 63-year-old musical and artistic savant with a diagnosis of ASD was found to have striking asymmetries in the amygdala, with the right side 24% larger than the left, as well as an asymmetrical caudate nucleus and putamen. Magnetic resonance spectroscopy revealed concentrations of the neurotransmitters GABA and glutamate more than two standard deviations below controls. Diffusion tensor imaging (DTI) showed greater white matter densities in most neural

structures as compared to controls with the greatest disparity occurring in the hippocampus (Corrigan et al. 2012). Kim Peek (see above) had no corpus callosum and no anterior or posterior commissures. Additionally, the morphology of the cerebellum and left hemisphere was distorted (Brogaard 2012; Corrigan et al. 2012). A number of other cases have been examined with MRI, fMRI, and PET, and although the abnormalities have not been consistent across patients, most savants imaged had some anatomical abnormalities or altered activation of neuronal pathways when performing their talents (Corrigan et al. 2012). Which of these abnormalities, if any, contributed to the specific areas of genius or to the developmental disabilities in these individuals is unclear.

Evidence from the case studies described above, that specific brain structures show exuberant growth, is at its face, consistent with the view that savant syndrome derives from increased development of certain structures and the connections between them, at the expense of connectivity in other areas of the brain. This theory was initially proposed to account for the striking overlap of structural and functional features between individuals with ASD and individuals with high IQ. For example, researchers have identified a statistically significant overlap between genes that are associated with autism and genes that are associated with high IQ (Crespi 2016). Similarly, both people with autism and those with higher IQs tend to have larger brain volumes and more brain growth (Crespi 2016).

These findings are somewhat paradoxical given that individuals with autism on average tend to have lower IQs than the population at large. Crespi (2016) seeks to resolve this paradox by suggesting that people with autism may have higher than average IQs in certain areas. These areas of functional gain could result from higher levels of local neuronal connectivity as compared to controls. While support for this theory in the realm of autism is constrained by limited evidence of discrepancies on IQ subtests (Charman et al. 2010), it may be more applicable to savant syndrome, where these kinds of discrepancies are a hallmark of the condition. DTI studies as well as

resting state fMRI studies on a larger number of savants would be helpful in testing this hypothesis further.

Greater neuronal connectivity in the savant brain could support the theory that savants have enhanced perceptual functioning (Mottron et al. 2009). Many savant skills, including skills in music, art, math, and reading, follow a series of consistent patterns. Superior pattern recognition, therefore, may underlie some savants' exceptional skills. For example, Derek Paravicini, a musical savant with perfect pitch, is far better at recognizing musical cords than a non-savant, which likely contributes to his prodigious musical talents. Superior pattern completion, or the ability to recall a missing component of a known signal, could also contribute to some savants' areas of greater ability (Mottron et al. 2009). For example, Stephen Wiltshire can complete a two-dimensional drawing of the three-dimensional city after seeing it only once. He achieves this by beginning with notable buildings and structures and then filling in details (Höfer and Röckenhaus 2015). Prodigious talents could also be accounted for by an enhanced ability to detect deviations from a usual pattern, as has been documented in some cases of autism (Mottron et al. 2009).

Genetic linkage studies in savant populations have been limited due to small sample sizes. However, one study found that there may be evidence to suggest that the region 15q11-q13 contributes to the development of savant skills (Nurmi et al. 2003). Previous studies have indicated that duplications in this region may produce the autism phenotype, and deletions in the paternal chromosome or maternal chromosome result in Prader-Willi syndrome or Angelman syndrome, respectively (Nurmi et al. 2003). A significant difference was found in HLOD scores, a statistic that denotes evidence of genetic linkage, for 21 families positive for savant traits compared to 73 autistic families without the trait. The most significant HLOD score within the savant skills group was associated with the GABRB3 gene, which codes for a subunit of GABA receptors (Nurmi et al. 2003). GABA is the primary inhibitory neurotransmitter in the brain. Variations in

this gene have previously been indicated in individuals with Prader-Willi syndrome as well as other conditions. A second study, however, failed to replicate these findings (Ma et al. 2005).

Future Directions

Although research in this area has progressed significantly since savant syndrome was first described, many questions remain unanswered and the condition is still largely unexplained. Researchers still seek to understand the biological basis for the disorder as a whole and the specific mechanism or mechanisms that result in stark disparities between areas of prodigious talents and otherwise low intellectual abilities. The greatest benefit will come from studies that integrate analyses of brain morphology, connectivity, and function.

Like autism, savant syndrome is a heterogeneous disorder. Hence, no single explanation can explain all manifestations. Researchers need to investigate not only general mechanisms underlying savant syndrome but also variations in the disorder. For example, what causes one savant to be a gifted musician and another to be a gifted artist? The answer to this question may relate to environmental factors as much as individual predisposition.

The principle challenge to addressing these questions is the rareness of the disorder. Small sample sizes have been the norm of past studies and will likely continue to be so in the future. Despite its rareness, however, the exceptional nature of this disorder warrants our attention. Not only may this endeavor provide insight into the etiology of the disorder, but it may also shed light on mechanisms underlying the development of extraordinary abilities in the broader population.

Schaffer v. Weast (Burden of Proof in Moving a Child to Another Placement)

Andrew Lolli

Quinnipiac University School of Law, Hamden, CT, USA

Synonyms

[Schaffer v. Weast and the Burden of Persuasion](#)

Definition

The party seeking relief bears the burden of persuasion under the Individuals with Disabilities Education Act (IDEA). A burden of persuasion is “a party’s duty to convince the fact finder to view the facts in a way that favors the party.”

In *Schaffer v. Weast*, the United States Supreme Court ruled that the party challenging the status quo bears the burden of persuasion under the IDEA. In *Schaffer*, the plaintiff, Brian Schaffer, suffered from learning disabilities and speech-language impairments. Believing that Brian required more intensive attention, Brian’s parents initiated a due process hearing challenging the public school’s Individual Education Plan (IEP). The Supreme Court ruled that Brian’s parents, as the party seeking relief from the school’s IEP, must prove that the school’s proposed IEP was inadequate to meet Brian’s needs.

The Court reached this decision for various reasons. First, the Court noted that, with few exceptions, under Anglo-American law, the burden of persuasion is traditionally placed on the party challenging the status quo. Second, there was no reason to believe that Congress intended to place the burden of persuasion on defendants. In addition, the Administrative Procedure Act (APA) governs initial IEP challenges. The APA places the burden of persuasion on plaintiffs. By incorporating the APA into the IDEA, Congress intended to place the burden of persuasion on plaintiffs. Third, pragmatically, placing the

burden on school districts as a matter of course would squander public funds because school districts would be forced to litigate every IEP prior to implementation. Congress has repeatedly amended the IDEA to reduce the expense of enforcement. Thus, Congress did not intend school districts to incur great costs litigating each IEP before implementation. Fourth, Congress provided for equal access to information for parents challenging an IEP. This includes parents' rights to review all records on their child, an independent evaluation of the child, and options rejected by the school board. Thus, Congress provided parents with some resources necessary to challenge an IEP.

Implications for ASD Students

Customarily, parents challenge IEPs. A school district challenging an IEP, however, would also assume the burden of persuasion.

The IDEA currently requires school districts to provide voluntary mediation sessions. These sessions attempt to resolve disputes without litigation. Additionally, parents are encouraged to play a major role in the design of services to meet the student's particular needs.

Litigation Strategies

Practitioners should be aware that school districts need not disclose evidence of how other similarly situated children with ASD have performed in either analogous or dissimilar placements. Parents challenging an IEP should obtain trained legal and psychological counsel as many practitioners report using knowledge and language beyond that of a lay person's understanding to their advantage. If parents cannot afford professional help, however, their complaint will not be dismissed because "parents have a recognized legal interest in the education . . . of their child." Parents who meet their burden are entitled to reimbursement for expenditures if the school district has not made a "free appropriate public education available to the child."

Schedule of Reinforcement

Mark Groskreutz

Special Education and Reading Department,
The Center of Excellence on Autism Spectrum
Disorders, Southern Connecticut State University,
New Haven, CT, USA

Definition

General Definition

A schedule of reinforcement specifies the relation between one or more responses (i.e., response classes) and one or more reinforcing consequences. In addition to describing when a reinforcing consequence is available, different schedules of reinforcement have been shown to result in different patterns of responding (Ferster and Skinner 1957). Schedules of reinforcement should be considered during the planning phase for interventions for individuals with autism spectrum disorders (ASDs). In addition, schedules of reinforcement may need to be revised after an intervention has been implemented to ensure continued desirable outcomes and overall long-term success.

Schedules of reinforcement can be particularly important in various applied situations. Careful design and implementation of an appropriate schedule of reinforcement may increase the likelihood of learning a new response (i.e., skill acquisition). For example, an otherwise effective educational intervention may have limited effect if the consequence does not occur often enough, with sufficient immediacy, or with sufficient magnitude or quality. The design of interventions to reduce inappropriate behaviors and increase appropriate alternative behaviors should include

careful planning of appropriate schedules of reinforcement to result in desirable short-term and long-term effects.

Historical Background

Much of the earliest work on schedules of reinforcement is credited to the work of B. F. Skinner (Ferster and Skinner 1957; Green et al. 1959; Skinner 1953). Ferster and Skinner conducted extensive research on the effects of varying the relation between a particular response or pattern of responses and access to reinforcing consequences (e.g., food). Their research showed that the several parameters consistently effected patterns of responses, even when overall amount of reinforcement accessed was similar across conditions. For example, they found that reinforcement could be arranged to result in relatively fast or slow responding with or without pauses after reinforcement depending on how food deliveries were arranged. Research on schedules of reinforcement has continued to show reliable relations between schedules of reinforcement and particular patterns of behavior in both animals and humans.

Current Knowledge

Simple Versus Complex Schedules

Schedules of reinforcement may be separated into two broad categories, simple schedules and complex schedules. Simple schedules arrange a single contingency, such as reinforcement for every fifth response. In a complex schedule of reinforcement, more than one schedule is arranged and more than one schedule may be in effect at a given time. It is likely that real-life situations are associated with many schedules of reinforcement impacting an individual's behavior at any given time.

Simple Schedules

There are two general types of simple schedules of reinforcement, continuous reinforcement schedules and intermittent reinforcement schedules. In a continuous reinforcement schedule (CRF), each occurrence of a response is reinforced. An

example of a CRF schedule is the child's parent praises the child every time a child correctly places a puzzle piece. In contrast to CRF reinforcement schedules, intermittent reinforcement schedules arrange a reinforcer for some but not all occurrences of the target behavior. To use the puzzle example again, an intermittent schedule of reinforcement would mean the child's parent providing praise after some but not all correct placements of puzzle pieces.

Recommendations often include using CRF schedules when beginning a new intervention, such as to increase or improve communication (Cooper et al. 2007). The rationale for using a CRF schedule during the initial phases of teaching has to do with increasing the likelihood the learner will contact the contingency between the target behavior and a reinforcing consequence. By increasing the probability of this behavior-consequence relation, the behavior may be more likely to increase (i.e., be reinforced). After the behavior begins to increase, it is often recommended that the schedule be shifted from a continuous schedule to an intermittent schedule.

Intermittent reinforcement schedules can be based on either a *ratio* or *interval* schedule. In a ratio schedule, reinforcement occurs after a specified number of behaviors have occurred (e.g., reinforcement will occur after 5 sit-ups are completed). In an interval schedule, reinforcement occurs after the first response after a specified time period passes (e.g., the first request that occurs after 30 min have passed will be reinforced).

In addition to the ratio or interval schedule arrangement, intermittent schedules will also be either *fixed* or *variable*. In a fixed schedule, the criterion for reinforcement remains exactly the same for each opportunity (e.g., reinforcement will occur after every fifth sit-up). However, in a variable schedule, the specific criterion for reinforcement will vary for each opportunity and the schedule is usually expressed as the mean (e.g., reinforcement may occur after anywhere between 2 sit-ups and 10 sit-ups but will occur after a mean of 5 sit-ups).

Taken in combination, interval schedules are often described as fixed ratio (FR), fixed interval

(FI), variable ratio (VR), or variable interval (VI) schedules. Each schedule, the associated pattern of responding, and examples will be presented below.

Fixed Ratio (FR) Schedules

Fixed ratio schedules of reinforcement specify that reinforcement will occur after a constant number of occurrences of the target behavior. For example, if the target behavior is correctly spelling one's name and an FR3 schedule is used, then the reinforcer would be presented after every third correctly spelled name.

Researchers have shown that FR schedules maintain a relatively high rate of responding. However, FR schedules are also associated with a post-reinforcement pause: After accessing a reinforcer, there is often a pause before the person again begins to engage in the target behavior (see Fig. 1).

Variable Ratio (VR) Schedules

Variable ratio schedules of reinforcement specify the mean number of responses that will occur to access reinforcement. Thus, across subsequent reinforcer deliveries, sometimes the number of target behaviors will be greater or less than the mean. To again use the example of correct name spelling, the behavior could be reinforced on a VR 3 schedule. Under this schedule, the reinforcer

Schedule of Reinforcement, Fig. 1 Illustration of characteristic pattern of responding under a FR schedule, note the stable rate of responding (indicated by the constant increasing slope) and the post-reinforcement pause (indicated by the flat sections of the data path)

Schedule of Reinforcement, Fig. 2 Illustration of characteristic pattern of responding under a VR schedule, note the stable and relatively high rate of responding and no post-reinforcement pause; also note rate of responding is generally higher in a VR schedule than a VI schedule

might be delivered after 1, 5, 2, and 4 correct instances of name writing, the mean of which is 3.

Researchers have consistently found that VR schedules of reinforcement result in a relatively high rate of responding. Variable ratio schedules do not result in post-reinforcement pauses, which is in contrast to FR schedules (see Fig. 2).

Fixed Interval (FI) Schedules

Fixed interval schedules of reinforcement specify reinforcement will be delivered for the first response after a predetermined amount of time has elapsed. Reinforcement on a FI schedule is still contingent on the target behavior, so while the fixed interval may be 5 min, reinforcement will not be delivered until after the target behavior occurs. For example, on a FI 5-min schedule, reinforcement for requests for a break may not be granted until after 5 min have passed, so a request at 4 min would not be reinforced. However, if the person requests a break after another 4 min have passed (i.e., a total of 8 min have elapsed), then the request would be reinforced.

Researchers have often found that FI schedules of reinforcement result in a characteristic pattern. Immediately following reinforcement, there is usually period of time with no responding (a pause similar that which is seen in FR schedules); the behavior then begins to occur at a low to moderate rate before achieving a high rate just

Schedule of Reinforcement, Fig. 3 Illustration of characteristic pattern of responding under a FI schedule, note the FI scallop comprised of increasing rate of responding leading to high rate responding (indicated by the progressively increasing slope) and the post-reinforcement pause (indicated by the flat sections of the data path following the steep/high-rate responding)

before the interval ends. This pattern of slow responding at the beginning of the interval and fast responding at the end has been called the FI scallop due to the unique shape when performance is graphed on a cumulative record (see Fig. 3). While this pattern of responding has been consistently found with research using animal subjects, the FI scallop pattern of responding with human participants has been less reliable (See Chance 2009).

Variable Interval (VI) Schedules

Variable interval schedules of reinforcement arrange reinforcement for the first behavior that occurs after a certain amount of time has passed. However, the length of each reinforcement interval may differ from the preceding and subsequent intervals. VI schedules are arranged such that individual intervals will vary around a mean interval. For example, a VI 10-min reinforcement schedule could be selected for the behavior of requesting a break. Under this schedule, reinforcement might be delivered for the first response after 6 min for one interval and after 15 min for a different interval. Over subsequent intervals, reinforcement would become available after 10 min had passed, on average. Again, it is important to remember that reinforcement does not occur after

Schedule of Reinforcement, Fig. 4 Illustration of characteristic pattern of responding under a VI schedule, note the stable and moderate rate of responding (as compared to the VR schedule) and no post-reinforcement pause

the interval time passes; instead, reinforcement occurs following the first target behavior observed after the interval time has passed.

Researchers have consistently found that VI schedules of reinforcement result in moderate rate behavior. In addition, the VI schedule is not associated with a post-reinforcement pause (see Fig. 4).

Additional Simple Schedules

Differential Reinforcement

Several schedules of reinforcement have been considered differential reinforcement schedules. These schedules of reinforcement are designed to increase a particular behavior relative to other behaviors or increase the occurrence of a particular pattern of behavior. Differential reinforcement schedules include differential reinforcement of other behavior, differential reinforcement of incompatible behavior, differential reinforcement of alternative behavior, differential reinforcement of high-rate behavior, and differential reinforcement of low-rate behavior.

Differential Reinforcement of Other Behavior (DRO)

Differential reinforcement of other behavior schedules arrange reinforcement for the

nonoccurrence of a particular target behavior. DRO schedules are often arranged using a time-based criterion for reinforcement, for example, a child might be reinforced if they have not engaged in disruptive behavior for 10 min. In this example, the goal of the DRO schedule is to increase the occurrence of other behaviors (i.e., any behavior that is not the disruptive behavior).

Differential Reinforcement of Incompatible (DRI) and Alternative Behavior (DRA)

Differential reinforcement of incompatible behavior schedules arrange reinforcement for a target behavior that is incompatible with another behavior (the second behavior is often an inappropriate behavior). A DRI schedule, for example, could arrange reinforcement for having hands folded on one's lap. In this example, placing folded hands on one's lap is incompatible with hitting peers and may therefore contribute to reducing the occurrence of hitting peers and increasing hand folding. In other words, folding hands and hitting others cannot occur at the same time.

Similar to DRI, differential reinforcement of alternative behavior arranges reinforcement for a particular target behavior and is often designed to help reduce an inappropriate behavior. In contrast to DRI, the reinforced behavior in a DRA schedule is not incompatible with the other behavior, so the two behaviors could, in theory, occur at the same time. However, the behavior targeted for reinforcement in the DRA schedule can be selected, in part, because it is unlikely to occur at the same time as the behavior targeted for reduction. A DRA could be arranged to increase a child's hand-raising as part of an intervention to reduce hitting peers. In this case, it is possible that the child could hit a peer with one hand while raising other hand, but this may be unlikely.

Functional communication training (FCT) is a special case of DRA. In FCT, an appropriate, communicative response is reinforced as part of an intervention to reduce the occurrence of an inappropriate response (see Carr and Durand 1985 for early research on FCT). In the case of FCT, the appropriate response is a communicative

response that accesses the same reinforcer as the inappropriate behavior. For example, a child's hitting might be maintained by removal of work, so FCT could be used to reinforce asking for a break from work.

Differential Reinforcement of Low-Rate Behavior (DRL)

Differential reinforcement of low-rate behavior arranges reinforcement for behavior occurring below a specific rate criterion. The goal of a DRL schedule is to reduce the rate of the target behavior without completely eliminating it. DRL might be used, for example, to reduce the rate of repeating requests to play with a particular toy. The DRL schedule could arrange reinforcement for a request only when a sufficient amount of time passed since the previous request. There are several ways in which the rate of behavior can be calculated, but the outcome is similar regardless of the method used to calculate the rate, and reinforcement only occurs when behavior occurs at or below a target rate.

Differential Reinforcement of High-Rate Behavior (DRH)

Differential reinforcement of high-rate behavior arranges reinforcement for behavior occurring above a specific rate criterion. The goal of DRH schedules is to increase the rate of a particular behavior. DRH could be used to increase the rate of behaviors such as correctly typed words per minute. In this example, reinforcement could be arranged only for correct typing that occurs above the criterion level for words per minute.

Time-Based Simple Schedules

While schedules of reinforcement are typically based on the occurrence of target behavior, they may also be used to arrange reinforcement at particular times, regardless of behavior. In time-based schedules, a stimulus or event with demonstrated reinforcing properties is delivered at specific times whether or not the target behavior has occurred. These time-based schedules are

sometimes called *noncontingent reinforcement* (NCR) because the consequence is not contingent on a particular response.

Time-based schedules can be arranged as either fixed-time or variable-time schedules. In a fixed-time (FT) schedule, the reinforcer is delivered at a specific time, such as every 30 min (e.g., FT 30-min schedule). Reinforcers can also be arranged on a variable-time (VR) schedule, such that the reinforcer is delivered after differing amounts of time, varying around an average. For example, reinforcement could occur after 10 min, 15 min, and 20 min for an average of 15 min (which would be a VR 15-min schedule).

Time-based reinforcement schedules have been used in interventions to reduce inappropriate behavior. Researchers have shown that when reinforcers are delivered every so often (i.e., on a FT or VT schedule), the target behavior may decrease (e.g., Vollmer et al. 1993). This reduced level of inappropriate behavior has often been attributed to a decrease in motivation for the reinforcer for the target behavior. For example, if a child engaged in hitting because it has resulted in attention in the past (i.e., attention is the reinforcer), using a VT schedule, an adult might provide attention every 5 min on average. With the VT schedule in place, the child may receive sufficient access to adult attention and therefore not engage in hitting others.

Complex Schedules

There are a variety of ways in which several schedules of reinforcement can be combined. When two or more simple schedules are combined, the resulting schedule is called a *complex schedules*. Complex schedules can include two simple schedules operating simultaneously, called a concurrent schedule. Complex schedules can also include two or more simple schedules that occur in a particular order, such as multiple schedules or mixed schedules. Furthermore, complex schedules can include a combination of schedules occurring at the same time at some times and in a particular order at other times (e.g., concurrent chains schedules). These complex

schedules can be analogous to common situations in which a person must choose between two or more behaviors and reinforcement contingencies.

Future Directions

Research on schedules of reinforcement can still be seen today, though it may not be discussed as such. An important outcome for individuals with ASDs is increasing and maintaining appropriate behaviors while decreasing and eliminating inappropriate behaviors. Researchers and practitioners should continue to look at the relation between reinforcement and acquisition of appropriate behaviors (e.g., social skills, academic behaviors, personal care) with a particular focus on potential relations between reinforcement schedules during learning and extent to which learned behaviors maintain when some or all supports are removed. Recent research in behavioral momentum (see Nevin and Grace 2000 for a review of behavioral momentum) has illustrated that overall reinforcement in a context may play an important role in maintenance of behavior (i.e., behavioral persistence). Other researchers have used progressive ratio schedules to examine maintenance of behavior (see Roane 2008 for a discussion). Ultimately, much of the success of individuals with autism will be based on their acquisition of appropriate behaviors, and schedules of reinforcement play a key role in both the speed at which behaviors may be acquired and the extent to which the learning will be demonstrated independently after interventions are removed or reduced.

School to Work Transition Process

Anne Holmes
 Eden Autism Services, Princeton, NJ, USA

Definition

School psychology is the specialization of the professional practice of psychology that is concerned with children, youth, and families and the schooling process. The field of school psychology combines a unique knowledge base with that of related fields including clinical and educational psychology in order to focus on the individual study of children's learning and adjustment primarily in educational settings.

School psychologists primarily administer psychological and educational tests and conduct observations and interviews in order to better understand areas of concern and abilities that may be present for a student. School psychologists also consult with parents and educators and develop behavioral and teaching-based strategies to improve academic and socioemotional outcomes and support students with learning and behavioral disabilities.

Definition

'Transition' refers to a change in status from behaving primarily as a student to assuming emergent adult roles in the community. These roles include employment, participation in post-secondary education, maintaining a home, being appropriately involved in the community, and experiencing satisfying personal and social relationships. (Council for Exceptional Children's Division of Career Development and Transition 1994)

The transition process from school to adulthood, specifically employment, involves the application of educational experiences into successful employment. The educational experiences that are applied in adulthood involve more than employment: both community living and experiencing personal and social relationships impact successful quality of life as an adult.

Historical Background

If one looks back 20 years, students with autism were being educated either in generic disability classrooms or in residential institutions. There were no discussions regarding adults with autism, as many were institutionalized or living at home with their aging parents.

As the awareness of the unique needs of individuals with autism has increased, evidence-based practices have been established and are being integrated into the public school environment, planning for the school to work transition can now be achieved.

Current Knowledge

In 1975, PL 94:142 authorized the Education of All Handicapped Children Act. This Act mandated a free and appropriate public education for all children regardless of disability. In 1990, the Individuals with Disabilities Education Act, PL 101:475 not only reauthorized the PL-94:142 but extended the requirement for education of children with disabilities and required transition services for children with disabilities. The amendment specifically outlined that special education needed to prepare students for employment and independent living.

Even with this law and clear attempts made by educators to offer educational services that impact success as an adult, two-thirds of Americans with disabilities between the ages of 16 and 64 are not employed (Wehman 2001). Specifically, many individuals with autism spectrum disorders have completed high school and/or college but are unable to make the transition to employment. For individuals with autism spectrum disorders, particular reasons for this failure may include difficulty with social competencies, communication deficits, behavioral issues, and potential comorbid mental health issues.

Difficulty with social competencies is core to the diagnosis of autism spectrum disorders. Individuals with autism spectrum disorders often have difficulty understanding the nuances of typical social behavior and as such struggle with interacting with others. Individuals with autism spectrum disorders also have difficulty with problem solving and coping, which can all translate to difficulty in the workplace. Teachers and vocational rehabilitation specialists often focus on job competencies rather than social competencies. For individuals with autism spectrum disorders, the job competencies may be secondary and the social competencies need to be a primary focus during the school age years.

In addition to challenges with social competencies, individuals with autism spectrum disorders often struggle with communication. They may have difficulty initiating or maintaining a conversation, often will not use facial expressions, body language, or other nonverbal

behaviors to complement their social communication interaction. Effective communication is paramount to success in a job placement, as that is what allows for clarification of job requirements, performance, and working effectively with coworkers.

Another area that may negatively impact success in a job placement is behavioral issues. While behavioral issues vary, many individuals with autism spectrum disorders may insist on sameness, regardless of the job at hand, and intense preoccupation with topics or subjects may also interfere with job requirements, as both lead to off-task behavior. Supporting the individual with autism spectrum disorder to self-monitor and control behavioral issues, as well as educating the community to increase understanding and tolerance of these behaviors, is necessary for successful employment of individuals with autism spectrum disorders.

Individuals with autism spectrum disorders may also exhibit comorbid mental health issues. Specifically related to autism in adolescents, there is an increased vulnerability to anxiety disorders and depression (Wehman et al. 2009). It is essential that individuals with autism spectrum disorders are afforded the appropriate mental health support services to treat such disorders.

Research points to the fact that individuals with autism spectrum disorders can work and obtain a quality of life, but they need support to do so (Wehman et al. 2009). A significant factor to this success will be effective transition planning during the school years. Ideally, transition planning should begin in early intervention, when a young child with autism spectrum disorder begins to be taught important skills that impact social skills, behavior, communication, and independence. These educational themes should be featured throughout a young student's Individualized Education Plan (IEP).

The IEP is the legal document that is a guideline for all transitions. Transition IEPs should include assessments, goals and objectives, and intervention strategies that target priorities for skills that are necessary for success as an adult. The transition IEP team is typically made up of the student, parents, special education teacher,

general education teacher, community agency personnel, potential employers, and/or vocational rehabilitation counselors. This team is charged with assessing and developing goals and objectives that will meet transition to employment goals as well as effective implementation strategies to do so.

Prior to developing IEP goals and objectives, there needs to be some level of career awareness for the student with autism spectrum disorder. Typically, career awareness begins in the elementary school years when children are exposed to a variety of “community helpers.” In the middle school years, students are exposed to career awareness through the content of some academic subjects such as science or English through which they learn about various careers, for example, scientists or authors. In high school, there is a more specific focus on career awareness as focus is placed on preparation for post-secondary education or vocational and technical training. Individuals with autism spectrum disorders should receive some type of vocational assessment through which potential jobs can be matched to the individual’s strengths and interests. These students should also be exposed to job sampling, which allows them to try out a variety of jobs for brief periods of time to actually experience that job. Another avenue for vocational assessment is performance sampling, which is simulated work done in the classroom. This type of assessment results in a more cursory review for job matching.

For students with autism spectrum disorders, there clearly needs to be goals and objectives in the IEP that focus on social competencies, adaptive skills, and work habits. In the area of social competencies, goals and objectives must effectively address the challenges of social interactions, problem solving, coping, and self-management. Adaptive skills should focus on grooming, mobility, health and safety, and money management. Work habits should be addressed through goals and objectives that highlight productivity, attendance, and accuracy in a job.

Once appropriate goals and objectives have been developed and accepted by the IEP team, focus needs to be placed on successful

achievement of these goals and objectives. When preparing a student with autism spectrum disorders for employment, it will be necessary for knowledgeable staff to oversee the implementation of goals. The school environment must either have personnel with expertise in autism spectrum disorders or have access to this expertise through consultation. Successful achievement of goals and objectives will only be reached if strategies meet the unique needs of students with autism spectrum disorders. In addition, for successful achievement of transitional IEP goals, there clearly has to be practice of skills beyond the self-contained classroom.

Educational inclusion allows for an individual with disabilities to be appropriately supported to learn in a general education environment. In inclusion, the student with autism spectrum disorder can gain general knowledge and improve their social interactions through peer modeling and practice. Inclusion provides students with autism spectrum disorder the opportunity to be members of the school community and to improve their independence. Achievement of IEP goals and objectives will be partly based on the appropriate balance of specialized direct instruction and inclusion opportunities.

Alongside educational inclusion as a critical component of the school to work transition process is community-based instruction. Community-based instruction is the systematic teaching of students with autism spectrum disorders within the natural community setting. Community-based instruction enhances the transition of a student with autism spectrum disorder to employment, as skills are taught and reinforced in the actual environment where the student will live and work as an adult (Wehman et al. 2009).

When IEP goals and objectives are implemented through community-based instruction, skills are taught where they are expected to occur. This also allows for immediate generalization into the natural environment. Community-based instruction can be implemented at a community college, work site, stores and restaurants, and recreational facilities. When community-based instruction is not possible, it is important that places outside of the classroom in the school

environment be used to foster this natural setting. Places such as the cafeteria, library, office, or school grounds can be used for natural environment instruction.

When community-based instruction is focused specifically on employment, it is essential that the IEP team assess the local community in regard to the availability of jobs. The IEP team will also have to match the job to student interests and capabilities and determine whether instruction needs to begin before the job placement or if on-the-job training can be implemented from the beginning.

There are supports beyond the IEP that are positive factors leading to successful employment for young adults with autism spectrum disorders. It is important that, as students with autism spectrum disorders approach their 21st birthday and enter a world with no entitlements, community supports are secured. Vocational rehabilitation services are available in all states in the USA. It is important that a relationship is developed with vocational rehabilitation services in order to prepare for the transition from school supports to post-21 supports. This may specifically be noted in transitioning from school staff to a job coach who can be available for the individual with autism spectrum disorder once they have graduated and are at a specific job placement.

Another important support that needs to begin prior to the 21st birthday of an individual with autism spectrum disorder and should be part of the transition from school to work is the development of appropriate supports on the job site. The good news in 2011 is that the general public is much more familiar with autism spectrum disorders than it was in 2000. As part of this general public awareness, coworkers, supervisors, and employers have the potential to have some knowledge base regarding autism spectrum disorders before the student is employed. It is important that this awareness be expanded upon and include specific information about a particular student with autism spectrum disorder so that appropriate supports can be provided by these coworkers, supervisors, and employers. Not only will this continue to increase understanding and tolerance

for the unique characteristics of autism spectrum disorders, but it will also allow a coworker or supervisor to provide support that potentially a job coach would have provided. Job coaches need to be faded, and as such, if the natural supports in the work site can support the individual with autism spectrum disorder, the more successful they will be.

Future Directions

Increased awareness of the supports that individuals with autism spectrum disorders need to achieve successful employment can be viewed as a positive prognostic indicator for the future. It is evident that the payoff of appropriate education of students with autism spectrum disorders will be a new generation of successfully employed individuals. The pressure must be felt during an individual with autism spectrum disorder's entitlement years of education to effectively prepare that individual for adulthood.

School-Aged Children

Martine Solages

Child Study Center, Yale University, New Haven, CT, USA

Definition

The school-aged period encompasses the years between early childhood and adolescence, during which many children step out into the world outside the family for the first time. The characteristic symptoms and clinical signs of autism spectrum disorders are typically detected prior to the school-aged period, during early childhood. The diagnostic criteria for autistic disorder listed in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR 2000) specify that the onset of symptoms occurs prior to the age of 3 years (DSM-IV-TR 2000). There is significant focus on the identification of children on the autism spectrum during the early childhood years. However, not all children with autism spectrum disorders are identified prior to school enrollment. Moreover, the school-aged years present children with autism spectrum disorders with ongoing challenges. The presence of an autism spectrum disorder affects the trajectory and completion of

the key developmental tasks of the school-aged years and often requires specialized attention in a number of domains, including mental health, medical, and educational settings.

Historical Background

The school-aged years were once conceptualized by Freud and others as a period of latency, during which sexual drives are suppressed and energies are diverted to the skill mastery challenges of school and peer relationships. Psychologist Erik Erikson identified the actualization of “Industry versus Inferiority” as the critical developmental accomplishment of the school-aged years. Industry refers to a child’s increasing competence in a variety of realms that is expected over the course of childhood. Though brain size does not change significantly after the age of 7, the school-aged period is a time of continued maturation of brain processes. Typically developing children become capable of higher level cognitive tasks. They become more adept at mathematics and concrete reasoning, they begin to develop a fund of knowledge about the world, they learn to read and to write, and they begin to develop moral reasoning as well. Their motor skills become more precise and they are able to complete more intricate motor tasks. Social development is marked by the growing importance of peers and the capacity to develop friendships. School-aged children are eventually able to follow rules and to engage in team-based play. The completion of developmental achievements in the cognitive, motor, and social domains allows for a greater independence from parents. If these developmental tasks are not completed, feelings of inferiority and self-doubt may emerge (Combrink-Graham and Fox 2007).

Autism spectrum disorders characteristically impact all the developmental domains. Significant impairments in social interactions and language development are pathognomonic of classic autistic disorder and occur with varying severity in other spectrum disorders. Intellectual disabilities are also common in children with autism spectrum disorders as are unusual body movements and subtle motor abnormalities such as toe walking

and poor coordination. Children with spectrum disorders may require additional supports and interventions to navigate the developmental tasks of childhood (DSM IV-TR 2000).

In the context of the civil rights movements of the mid-twentieth-century United States, advocacy for more supports and services for children with developmental disabilities intensified, leading to federal legislation supportive of these aims. In particular, the Individuals with Disabilities Education Act (IDEA) of 1975 is a landmark piece of legislation that has had major implications for the educational opportunities available to children with autism. Prior to the enactment of this legislation, many children with developmental disabilities were excluded from the school system. IDEA stipulates that all children should have access to a free public education that is appropriate to their needs. IDEA was amended in 2004 to promote the use of evidence-based strategies to improve outcomes. IDEA entitles children to an individualized educational plan (IEP) and promotes placement in the least restrictive educational environment possible to meet a child's needs (Bryan 2010; Steedman 2007).

Current Knowledge

The particular psychiatric, medical, and educational needs of children with autism spectrum disorders often become evident during the school-aged years.

Mood and Anxiety Disorders in School-Aged Children on the Autism Spectrum

It may be a challenge to detect mood disorders such as depression in children with impaired language skills. However, there is some research that suggests that depression may occur frequently in autistic persons (Skokauskas and Gallagher 2010). Comorbid anxiety is common in children with autism spectrum disorders. Despite the presence of social impairment, some children are aware of and distressed by difficulties connecting with others. Anxiety can lead to avoidance behaviors and further isolation from peers and

community. There is wide variation in the estimates of the prevalence of anxiety disorders in children on the autism spectrum. As many as 40–50% of children in this population may meet criteria for anxiety disorders, including generalized anxiety disorder, separation anxiety, and simple phobias. It can be difficult to determine whether symptomatology represents a separate and coexisting anxiety disorder rather than a manifestation of the autistic disorder itself. Higher functioning children with autism spectrum disorders may be more likely to experience anxiety. There is some evidence that cognitive behavioral therapy and medications (such as the selective serotonin reuptake inhibitors) may be helpful for the treatment of anxiety disorders in children on the autistic spectrum (White et al. 2009).

Behavioral and Social Problems

Aggression and other self-injurious behaviors are also common in children with autism spectrum disorders and can be particularly disruptive in school environments. These behaviors can also pose a safety risk to the children, peers, families, and other caregivers. Aggression is often a target of psychopharmacologic treatment. The atypical antipsychotic medication risperidone is approved by the Food and Drug Administration for the treatment of aggression in children with autism. Other frequently used medications include other atypical antipsychotic medications, alpha adrenergic agonists such as clonidine, mood stabilizers, and stimulants (Parikh et al. 2008).

Since hyperactivity and inattention can be associated symptoms of autism, the DSM-IV-TR stipulates that a separate diagnosis of attention deficit hyperactivity disorder (ADHD) should not be given if autistic disorder is present. Attentional symptoms are nonetheless frequent targets of psychopharmacologic treatments, and there is some evidence that children on the autism spectrum respond differently to medications typically used for ADHD (Reiersen and Todd 2008). Children with spectrum disorders may also have deficits in executive functions such as planning and mental flexibility, though they tend to perform comparably to controls on tests of inhibition (Hill 2004).

Social skills do not improve automatically with age in children with autism spectrum disorders. In fact, impairment may become more pronounced over time with the increasing social demands of the school-aged period. Children may become more acutely aware of their social limitations, resulting in feelings of loneliness and distress. Examples of problems with social interactions exhibited by children with spectrum disorders include fixation on restricted interests and inability to read the interest of peers, difficulty with reciprocal conversation, and abnormalities of expressive language. Social skills training (SST) programs may be available to school-aged children with autism. More research is needed to determine the most effective methods for social skills building (Williams White and Keonig 2007).

Medical Disorders

In addition to developmental, behavioral, and mood symptoms, children with autism and autism spectrum disorders appear to be at increased risk for a number of medical problems that can occur during the school-aged years. Diagnosis of these medical issues is often a challenge in this population, as children may present with symptoms that are not typical. More time and effort may be needed to arrive at an accurate diagnosis, particularly for children who are non-verbal or who have significant behavioral disruptions. Common medical disorders seen in children with autism spectrum disorders include seizures, sleep disorders, and gastrointestinal disorders (Goldson and Bauman 2007). As many as one third of children with autism will have a seizure at one point in their lives. Children with co-occurring intellectual disabilities appear to be more likely to have seizures. Though the incidence of seizures is highest in early childhood and in adolescence, seizures can occur at any time during childhood (Volkmar and Nelson 1990). While a sizable minority of typically developing children will experience sleep problems, two thirds of children on the autism spectrum have sleep difficulties, including insomnia, hypersomnia, enuresis, and nightmares. Poor

sleep has been linked to behavioral difficulties and poor school performance (Richdale and Schreck 2009). Gastrointestinal disorders – such as constipation, diarrhea, and abdominal pain – occur frequently in the general child population; the relative prevalence of these issues in children with autism spectrum disorders has not been clearly established. Gastrointestinal problems may present with behavioral and sleep disturbances in school-aged children with autism (American Academy of Pediatrics [AAP] 2010).

Educational Needs and Accommodations

The educational environment presents a number of opportunities and challenges for children with autism spectrum disorders. Educational programs can provide the foundations for continued education, the development of life and independent living skills, the cultivation of social skills, and employment. Collaboration between parents, teachers, school administrators, and medical and mental health providers is paramount, particularly when developing the individualized educational plan (IEP). The IEP should define specific goals for the academic year and identify a system of modifications and supports to help the child achieve those goals. There are a variety of educational approaches available; interventions should be targeted toward children's specific and individual needs. Evidence-based interventions in schools might include applied behavioral analysis, positive behavioral supports, and assistive devices and technology. The child should be placed in the least restrictive educational environment, and there has been a move toward the inclusion classroom, in which special education services are embedded in the regular classroom. Parents, teachers, and school administrators must work together to determine the appropriate balance of inclusion instruction and separate special education instruction for each child (Noland et al. 2007). Children with autism may process information differently and may benefit from the use of pictures and concrete teaching tools. They also frequently benefit from structured environments and clear expectations (Mukuria and Obiakor 2008).

Future Directions

Children with autism spectrum disorders often require a number of specialized services during the school-aged years in order to meet their medical, psychiatric, and educational needs. More data about appropriate interventions in these realms are needed. Care coordination between primary care and specialty providers may facilitate accurate diagnosis and effective treatment of medical conditions. Further efforts to clarify the prevalence and presenting symptoms of certain medical disorders may help inform future diagnostic and treatment guidelines for children with autism spectrum disorders. In particular, the relationship between autism and gastrointestinal and neurologic disorders is an area of active research. Many psychopharmacologic agents are commonly used to treat psychiatric symptoms in this population, but definitive evidence of benefit is not yet available for many medications. Management of long-term medication side effects such as obesity and metabolic derangements should also be a focus of clinical and research attention. More information about the impact of non-pharmacologic interventions such as social skills training would be valuable. There has been a growing emphasis on using scientifically based treatments in the classroom setting, and more data on the implementation and effectiveness of these interventions is also needed.

School-Clinic Care Coordination for Youth with ASD

Maryellen Brunson McClain¹ and Jeffrey D. Shahidullah²

¹Department of Psychology, Utah State University, Logan, UT, USA

²Department of Psychiatry, Dell Medical School, The University of Texas at Austin, Austin, TX, USA

Definition

School-clinic care coordination is the interprofessional communication and collaboration between providers in the educational (i.e., schools) and medical (i.e., primary/specialty care clinics) homes to promote streamlined and integrated care for individuals with special health care needs, such as autism spectrum disorder (ASD).

Current Knowledge

ASD is a complex and multifaceted neurodevelopmental disorder that often requires interprofessional care for behavioral, medical, psychiatric, and learning-related issues. For example, many children with ASD have co-occurring GI problems, neurological disorders (e.g., seizures), genetic syndromes, feeding and sleep issues, academic difficulties, mood disorders (e.g., anxiety, depression), disruptive behaviors (e.g., ADHD), and intellectual disability, among others. As a result,

many youth with ASD often receive care from providers (e.g., school nurses, school psychologists, primary care clinicians, developmental behavioral pediatricians) across school and community settings.

Many families with ASD report feeling overwhelmed and marginalized when attempting to coordinate the care their child receives from providers across multiple settings. This often occurs when providers from multiple disciplines do not discuss their service delivery plans with one another, leading to fragmentation or duplication of care. Streamlining services across these providers and settings is critical to increase the efficiency and quality of care as well as to promote family satisfaction and their experience of care (i.e., family centered care).

Streamlined services can be accomplished through care coordination whereby providers collaborate interprofessionally through information sharing and collaborative decision-making around unified approaches to evaluation and management that address behavioral, medical, psychiatric, and learning-related issues. For example, school-based academic and behavior performance data can be shared by school psychologists with a specialty ASD clinic in order to enhance diagnostic clarity and treatment planning. Similarly, a physician can share information with a school professional about a co-occurring medical condition and its potential impact on learning in order to inform educational programming and related supports. Because many youth with ASD are prescribed psychotropic medications for co-occurring mental health conditions (e.g., ADHD), school psychologists are often well positioned to undertake collaborative medication-related roles. For example, they can collect behavioral performance data as well as side effect checklists and share these data with prescribers (child-adolescent psychiatrists, developmental behavioral pediatricians, nurse practitioners, pediatricians) for dosage titration and progress monitoring purposes (pending parental consent for information sharing).

There are several barriers that prevent effective school-clinic collaboration among professionals. These include, but are not limited to, lack of knowledge of roles and functions of service providers in

other settings; differences between medical diagnosis eligibility criteria and special education criteria; difficulty with sharing information given Family Educational Rights and Privacy Act (FERPA) and Health Insurance Portability and Accountability Act (HIPAA) privacy restrictions; and provider time constraints. Providers are encouraged to engage in behaviors that decrease barriers and facilitate effective interprofessional collaboration, for example, understanding both HIPAA and FERPA laws and determining what steps and legal documents are required prior to information sharing; respecting, understanding, and having awareness of other service providers and their roles; valuing interprofessional collaboration and team-based care; engaging in shared decision-making; sharing and discussing relevant information; collaboratively determining a communication plan at the outset (e.g., when, about what, with what frequency, and via what medium); and ensuring support from caregivers and administrators.

To increase engagement in school-clinic care coordination for children with ASD, there will likely need to be changes to administrative support structures in schools and clinics/health systems that allow for shared decision-making and team-based care (e.g., HIPAA/FERPA compliant web-based portals for information sharing and collaboration). Changes to training structures in professional programs are also needed to better emphasize crosscutting skills associated with interprofessional collaboration and team-based care. It is strongly recommended that providers receive training specific to interprofessional care, both at the preservice and professional development levels.

Education/Degrees

University of Chicago, B.A. 1949

University of Chicago, M.A. School of Social Service Administration 1955

University of Chicago, Ph.D. Clinical Child Psychology 1964

Major Appointments (Institution, Location, Dates)

- Professor: Department of Psychiatry, University of North Carolina, Chapel Hill, 1964–2005
- Codirector and Director of Division TEACCH, University of North Carolina, Chapel Hill, 1972–2005
- Editor, *Journal of Autism and Developmental Disorders*, 1974–1998
- Editor, *Current Issues in Autism Series*, Plenum, 1983–1998

Major Honors and Awards

- 2006 American Psychological Foundation Gold Medal Award for Life Achievement in the Application of Psychology
- 2006 International Society for Autism Research Lifetime Achievement Award
- 2005 Autism Society of North Carolina Lifetime Achievement Award
- 1993 The North Carolina Award: the highest honor that is awarded citizens of NC
- 1985 American Psychological Association Distinguished Professional Contributions to Public Service
- 1985 O. Max Gardner Award from the UNC Board of Governors for great contributions to the welfare of the human race
- 1977 American Psychological Association Award for Distinguished Contributions to the advancement of knowledge and service
- 1972 American Psychiatric Association Gold Achievement Award (with Robert Reichler, M.D.)

Landmark Clinical, Scientific, and Professional Contributions

Dr. Schopler conducted some of the first research to use scientific methodology in the study of autism. He continued to promote the importance of quality research in the field of autism throughout his career, especially in his role as editor of the *Journal of Autism and Developmental Disorders*. He insisted that intervention strategies were founded upon sound research so that individuals with autism and their families could select effective interventions and avoid being manipulated by unsupported claims (Reichler and Schopler 1971; Schopler 1965, 1966, 2001).

Dr. Schopler was a lifelong advocate for incorporating the parent perspective in autism research and treatment. His research was central to the transition from seeing autism as psychogenic in nature (the refrigerator mother theory) to a scientifically based understanding that autism is

developmental in nature (Schopler 1971, Schopler and Reichler 1971).

Dr. Schopler along with Robert Reichler, M.D. directed the 5-year NIMH-funded Child Research Project beginning in 1967. This was a landmark study demonstrating that parents are a central component to the treatment of children with autism (Schopler and Reichler 1971). Results of the study became a model for parent-professional collaboration at a level that was unheard of at the time.

Dr. Schopler was one of the first researchers to document the positive response of children with autism to structured intervention approaches. His research led the field of autism away from unstructured psychodynamic interventions that were predominant at the time and toward interventions based on an understanding of the learning styles of individuals with autism (Schopler et al. 1971, 1994).

Dr. Schopler was the cofounder of Division TEACCH along with Robert Reichler, M.D. TEACCH (an acronym for Treatment and Education of Autistic and related Communication handicapped CHildren) was the first comprehensive statewide program for the treatment of individuals with autism and their families. Under his leadership, Division TEACCH provided accessible services to families in the state of North Carolina. TEACCH integrated provision of a range of services including assessment, parent training, and community-based school, vocational, and residential programs (Mesibov et al. 2005).

Dr. Schopler was the cocreator of the Childhood Autism Rating Scale (CARS) (Schopler et al. 1988), one of the first standardized diagnostic assessment instruments for autism. Since its original publication, the CARS has been a mainstay of diagnostic assessment. Dr. Schopler began his career with a commitment to evidence-based clinical practice and closed his career by continuing this pursuit, contributing to the development of the most recent version of the CARS, the CARS-2-HF (Schopler et al. 2010).

Dr. Schopler contributed to the development of the Psychoeducational Profile (PEP) (Schopler

and Reichler 1979) and the Adolescent and Adult Psychoeducational Profile (AAPEP) (Mesibov et al. 1988). These two assessment instruments were based on the premise that understanding an individual's pattern of strengths and weaknesses is essential to selecting successful intervention goals and strategies. The PEP is now in its third edition (Schopler et al. 2005), and the AAPEP has been updated as the TEACCH Transition Assessment Profile (Mesibov et al. 2007). Both instruments have been translated into several languages and are used by autism programs worldwide.

Throughout his career, Dr. Schopler was devoted to increasing the accessibility of services in North Carolina and around the world. He never tired in his efforts to support parents who have often been the driving force behind service development. His ability to develop collaborative relationships with parents and professionals has led to multiple replications of the TEACCH model that continue today (Schopler 2000).

Short Biography

With no doubt, Eric Schopler was an individual who had a lasting impact on the field of autism research and intervention. Dr. Schopler was the author of over 200 books and articles about autism. He was the cofounder of the internationally recognized autism treatment program, Division TEACCH. He was the recipient of numerous awards and honors, but above all else, he valued his collaborations with parents and their children with autism. This collaboration between parent and professional was the hallmark of his career. It set him apart from most of the respected professionals of his day who espoused a psychodynamic approach to autism. Dr. Ruth Christ Sullivan, parent and first president of the Autism Society of America commented on his uniqueness as a professional, "Here was a young professional mingling with parents as equals. At the time you could be chastised or ostracized for mingling with parents" (Sullivan 2005).

Dr. Schopler's sensitivity to the dangers of marginalizing groups began with his childhood in Germany. He was born in Furth, Germany, in 1927. In 1938, his parents, Ernst Schopler and Erna Oppenheimer Schopler, escaped Nazi persecution by emigrating to the United States with Eric and his siblings. A child at the time, Dr. Schopler did not recall direct abuse by the Nazi government, but he recalled friends and teachers who suddenly left or disappeared. Out of his struggle to understand what had happened to his family and all European Jews, a cognitive framework developed that made him ever watchful for abuses of power, particularly within members of his own field, psychology.

He observed just such an abuse with regard to the parents of children with autism and other severe disorders. As a social worker at the Bradley child psychiatric hospital in Providence, RI, Dr. Schopler observed how parents were blamed for their child's disorder. Dr. Schopler found this conclusion to be unsupported by empirical observation. His own observation of the children at Bradley and at the University of Chicago's Research Center for Childhood Schizophrenia made clear that their unusual and frustrating behavior was due to developmental phenomenon such as the way in which they used their senses (Schopler 1965, 1966). He could identify no way in which the children's behavior was associated with parenting. In his research on parents, he found no evidence that parents of children with autism had higher rates of thought disorders than parents of typical children (Schopler and Loftin 1969). His conclusion, therefore, was that blaming parents served a purpose unrelated to a true understanding of autism. In his article *Parents of Psychotic Children as Scapegoats* (Schopler 1971), Dr. Schopler used the theories of Gordon Allport to identify how mental health professionals had marginalized and undermined the parents of psychotic children (Allport 1954). Parents of children with autism were, in Dr. Schopler's view, being treated in much the same way that Allport described the treatment of the Jewish community and African-Americans

during the 1950s. To Dr. Schopler, the purpose of scapegoating parents was to blame an innocent and powerless group for the failures and frustration of professionals who were unsuccessful in treating autism.

Dr. Schopler's experiences from childhood through graduate school initiated two complementary threads in his career: (1) commitment to empowering disenfranchised parents by establishing the validity of their perspective and their usefulness in treatment, and (2) the means to accomplish the first goal was to ensure that intervention was based on sound empirical observation. The role of the parent was to be a lens through which research could be translated into useful practice rather than treatments devised by researchers which were often irrelevant to the lives of children with autism (Schopler 2005a). With this mindset, Dr. Schopler arrived at the University of North Carolina at Chapel Hill and joined the Department of Psychiatry where he met a like-minded psychiatry resident, Robert Reichler, M.D. The pair initiated the Child Research Study which demonstrated the efficacy of structured treatments in autism and the need to include parents as cotherapists in their child's treatment. When the study was completed, Drs. Schopler and Reichler had established the empirical evidence to begin the TEACCH program. Dr. Schopler would be the first to remind admirers that TEACCH was not his idea. The idea was generated by the parents participating in the Child Research Study. Parents provided that "lens" which would guide the application of this important research. They also provided the energy and commitment to convince the North Carolina legislature to fund TEACCH. But collaboration was still at the heart of this effort. It is unlikely that TEACCH could have been created without the evidence provided to the legislature by Dr. Schopler, Dr. Reichler, and even the endorsement of Dr. Leo Kanner.

Under his leadership, TEACCH continued to grow, but Dr. Schopler's efforts had an impact far beyond the border of North Carolina and Division TEACCH. In 1974, he took on the position as

editor of the *Journal of Autism and Childhood Schizophrenia* (later the *Journal of Autism and Developmental Disorders*) at the request of its outgoing editor, Leo Kanner. He was committed to developing this fledgling journal into a major outlet for soundly completed research. His research standards were high. Dr. Schopler refused, however, to lower the standards of scientific study simply to fill the pages of a journal devoted to a young field. Dr. Schopler used this new role to continue his efforts at marrying research to family needs. He initiated a “parents speak” section in which parents would occasionally weigh in on issues important to the journal. He also added the “Ask the Editor/Expert” section of the journal which invited parents to raise practical questions to be addressed by the editor (Schopler 1974).

Dr. Schopler’s commitment to high scientific standards and awareness of the needs of parents and their children were the foundation for many debates within the scientific and clinical literature. Having begun his career by challenging the leaders of his field, he did not shy from an argument now that he was one of the leaders. In the early days, psychodynamic theories and treatments of autism were an obvious focus of criticism for a researcher endorsing empirical methods. Later controversial topics such as facilitated communication were the object of swift critiques by Dr. Schopler (1992). He was watchful for research claims that exceeded the scope of intervention and played upon the hopes of parents by offering the hope of incredible gains where no evidence for gains of this magnitude could be found (Schopler et al. 1989). As the field developed, however, his critiques often took a different tone. Instead of invalidating a proposed intervention, he became a voice for moderation. He often weighed in on arguments by reminding researchers and clinicians of the need for individualization. He recognized from both his professional and personal history the dangers of dogmatically adhering to one approach (Schopler 1989). He endorsed research that explored the mechanisms that could predict which individuals with autism might respond to

an intervention and which might not. He commented on the complexity of this type of discourse and the need to gather many types of data including data that was not easy to quantify (Schopler 2005b).

Long past his death in 2006, Dr. Schopler’s influence continues to grow. His participation in teaching and mentoring young professionals has had an impact on many of the leading researchers and clinicians of our time. The authorship of “over 200 books and articles” is often quoted. It is less frequently noted that his writings have been cited nearly 10,000 times, clear evidence that his work will continue to be read far into the future. His commitment to training others in the TEACCH model has led to replications of the program worldwide. But one of his most lasting contributions is probably one of the least noticed. In large part because of his work, no parent (whose child is seen by a competent professional) will be treated as a scapegoat for their child’s autism. Encouraging parent participation in their child’s treatment is now the norm. Today, most parents of young children are unaware that that the position of parents was ever different than it is now. This is a gift parents today receive from Dr. Schopler and the parents with whom he collaborated. As mentioned earlier, Dr. Schopler’s most valued professional experiences were with individuals with autism and their families. The thanks of parents who knew him most eloquently express Dr. Schopler’s commitment to individuals with autism. In a remembrance offered at Dr. Schopler’s memorial, Mary Lou Warren recounted when she and her husband first met Dr. Schopler as participants in the Child Research Study in 1967 (Warren 2006). In just a few sentences, she captures Dr. Schopler as an individual and his core contribution to the field of autism:

I remember the first time that Frank and I saw Eric. He came out of his office to greet us on our first visit to Trailer 18, just outside the doorway of the Psychiatry wing. He was dressed in a plaid shirt and khaki pants and had mud on his shoes. And I remember asking myself, “Could this be the doctor?!” I was not quite prepared for this,

because what I'd been used to was white coats, stiff upper lips, and blank stares. Later that day as we walked down the sidewalk to our car, I had tears in my eyes as I looked at Frank and said, "My God! We have finally found someone who wants to help us."

Scoliosis

Susan Hyman
Developmental and Behavioral Pediatrics,
Division Chief Neurodevelopmental and
Behavioral Pediatrics, University of Rochester
Golisano Children's Hospital, Rochester, NY,
USA

Synonyms

[Curvature of the spine; Spinal curvature](#)

Definition

Scoliosis is an orthopedic condition characterized by a lateral curvature of the spine. It can be congenital (present at birth) or develop with growth. It may be secondary to malformations of the vertebrae (bones in the spine) or ribs and may be associated genetic syndromes. Scoliosis can also develop with neuromuscular conditions like cerebral palsy, spina bifida, and muscular dystrophy where there is imbalance of the muscular forces on the spine. The most common type of scoliosis is idiopathic. This means it occurs for unknown reasons most commonly with growth spurts as occur in adolescence. Clinically significant idiopathic scoliosis is more common in girls. It seems to run in families. On physical examination, one shoulder or hip may appear higher than the other, and there may be asymmetry with examination of the back while the

patient is bending forward at the waist. It may be associated with leg length discrepancy. Specialized x-rays are necessary to document both the curvature and if there is compensatory curvature in the opposite direction (S curve). Treatment depends on the age of the patient and the cause of the scoliosis. Idiopathic scoliosis with curves with less than a 20° angle on x-ray measurement is monitored during growth. Angles over 25° typically are managed with bracing to prevent further curvature. Braces can be taken off for sports. Bracing is much less helpful for scoliosis in younger children and due to neuromuscular disorders. Curves over 40° may require surgical correction. There are several different surgical approaches that involve fusing the bones of the spine together and/or using rods to help straighten the back.

Milder scoliosis can lead to back discomfort over time. More significant scoliosis associated with neuromuscular disorders may be lead to other significant symptoms associated with mobility, positioning, and orthopedic health. Severe scoliosis with curves approaching 100° may impact breathing. Therapies such as chiropractic manipulation and electrical stimulation have not been demonstrated to prevent progression of scoliosis. While physical therapy may be helpful for other symptoms of neuromuscular disorders, it does not prevent progression of scoliosis.

History

It is perhaps fair to say that, as a comparatively small country in terms of population, Scotland has played a leading role in many aspects of autism practice and research.

Scotland's autism story possibly began a long time ago. While this article will not focus on people with autism, one of the earliest presentations which has been claimed to be a case of autism is that of a Scottish minor aristocrat, Hugh Blair of Borgue (1708–1760s) (Hugh Blair of Borgue – Wikipedia 2016). Blair is described to have presented with various difficulties compatible with the diad (or triad) of impairments, such as obliviousness to social cues, bizarre collecting interests, and repetitive routines. However, Scotland's prominence in terms of autism history predominantly occupies the last 50 years. The pioneering work of Leo Kanner in the USA led to increasing awareness among Scottish parents about autism and their search for clinicians and educationalists who were interested in helping their affected children in their own country.

On the clinical side, individual child psychiatrists in Glasgow and Edinburgh began to investigate the needs of children with autism and develop services for them. Fred Stone (1921–2009) (Moore and Stone 2009) included autism in his wide ranging approach to the mental health needs of children and adolescents following his appointment to only the second consultant child and adolescent psychiatry post in Scotland in 1954. Over the next decade, Stone's work led, inter alia, to the founding of the Scottish Centre for Autism, which pioneered

multidisciplinary assessment and preschool intervention for ASD. On the east coast, Sula Wolff (1924–2009), consultant child psychiatrist at Edinburgh, began to study children with autism in the 1960s, culminating in her seminal work *Loners* (1995). Wolff preferred to use the term “schizoid” to classify socially dysfunctional children. This lack of clear linkage to the work of other emerging UK experts on autism, such as Michael Rutter, possibly rendered Wolff's work insufficiently recognized (Watts and Sula 2009). This emerging clinical interest in autism in Scotland was underpinned by observational research into infant-parent interaction led by Colwyn Trevarthen in Edinburgh, from the 1970s onwards, which generated primary psychological theories about intersubjectivity, with autism identified as a paradigm of intersubjective dysfunction.

In the 1990s, the pioneering work of Stone, Wolff, Trevarthen, and others fostered an emerging cohort of clinicians from all the key disciplines who began to develop services across Scotland, not just in the major teaching centers (McClure et al. 2010).

Following the ground breaking development of DSM-III in 1980 and increasing clarification and consensus about the nature of autism through the ensuing decade, what became increasingly clear throughout the 1990s was the lack of consensus about the autism evidence base. In 1971, writing about the 11 child subjects of his classic 1943 paper *Autistic Disturbances of Affective Contact*, Leo Kanner stated (1971):

We must keep in mind that they were studied before the days when a variety of therapeutic methods were inaugurated, based on a variety of theoretical premises: psychoanalytically oriented, based on operant conditioning, psychopharmacological, educational, via psychotherapy of parents, and combination of some of them. Sufficient time has not elapsed to allow meaningful long-range follow up evaluations. At any rate, no accounts are as yet available that would afford a reasonably reliable idea about the more than temporary or fragmentary effects of any of these procedures intended for amelioration.

Scottish clinicians took an active interest in international developments in the autism field

throughout the 1980s and early 1990s and, through a combination of individual efforts, answered Kanner's call for an overview of the evidence base in autism. This issue achieved a particularly Scottish focus with the publication of the Public Health Institute of Scotland's *Needs Assessment Report* in 2001 (Autistic Spectrum Disorder – Needs Assessment Report 2012). One of its key recommendations was that the Scottish Intercollegiate Guidelines Network (SIGN) should develop a practice guideline in autism. At the time, this was a novel suggestion, because hitherto, medical guidelines had focused on conditions amenable to quantitative, as opposed to qualitative research. SIGN's foresight in commissioning what became guideline 98 (2016) meant that Scotland led the way in producing the first national evidence based guideline for ASD. SIGN 98 pioneered use of guideline versions for children and young people, as well as parents and carers and produced an e-CPD module accessible via the SIGN website to anyone in the world. Awareness of autism, and its implications for clinical services, had come of age and one of the key clinical challenges for the next decade is how clinical services are going to address autism needs in a fair and equitable approach across the age range.

In parallel, and sometimes in partnership with academic and clinical pioneers, the powerful parent lobby in Scotland has also been instrumental in driving forward autism friendly services, since the Scottish Society for Autistic Children (SSAC) formed in 1968 (Feinstein 2010). Feinstein outlines the history of the parent experience in the 1960s and 1970s, when parent organizations grew but were only accessible to a small number of families. The 1990s saw the rise of many local parent groups affiliated to the larger National Autistic Society (2016) such as the Strathclyde Autistic Society and the Lothian Autistic Society (2016). These were formed in the same way as the older organizations – by parents in need. In 1992, Rhona Gallagher recalls that she and two other mothers of children with autism met up for a coffee in a local hotel and that was the start of the Lothian Autistic Society (LAS). It just got

bigger and bigger and eventually in mid-1990s there were over 200 members between parents and professionals:

Although I was a member of NAS and SSAC at the time, it was really nice to meet up face to face with other mums for support and sharing experiences as ASD wasn't as commonly known then as it is now. We were all concerned about educational placements and the lack of knowledge and understanding within the city (of Edinburgh). I think that once the LAS was formed and it was a local society, then parents felt that they had "a voice" and were able to make a lot of their concerns and frustrations known to various professional bodies. There was an enormous issue at the time where whole families were suffering due to the behaviour of the child with autism and there was no respite provision available. From this issue, the LAS voucher system was formed and this gave parents the respite that a lot of them were desperately in need of in order to function. The LAS is now more than 20 years old and still going strong and has become a huge support to parents, siblings, play schemes, social clubs, and respite. It has changed and evolved over the years and now is a professional charity with over 700 family members and professionals.

Parents like Rhona lobbied for parent/carer support and for new educational provision for the growing number of children being diagnosed with autism. They were supported in this by professionals, who also saw the need to develop new ways of working. In the 1980s, most autism schools in Scotland were residential, such as the charity funded schools Struan House and Camphill. One of the first local authority funded autism provisions, Middlefield Residential School in Glasgow, opened in 1988. This school was set up by Strathclyde Regional Council (SRC) as a national resource (for Scotland) and admitted pupils from Lothian, Ayrshire, Inverness, Dumfries, as well as Glasgow and outlying areas.

The staff at the Department of Child & Family Psychiatry (DCFP), which later became the Scottish Centre for Autism at the Royal Hospital for Sick Children at Yorkhill, Glasgow, and the parents they worked with were instrumental in raising the need for appropriate educational facilities for the children who were attending their intervention program (now the Scottish Centre for Autism and parent programme). Most of the

original pupils were those known to DCFP. This was one catalyst for the improvement of local provision and the development of professional parent partnerships.

The 1990s brought a significant shift in educational provision and practice for children with autism in Scotland, when other local authorities across Scotland began to open language unit provisions in mainstream schools and classes in special schools, specifically for children with communication disorders or autism. These provisions were staffed by Education and therapy staff, working in collaboration.

By the 1990s, the importance of early intervention was also increasingly being highlighted by parents and this also led to professional/parent partnerships in developing new models of service delivery and support. In Edinburgh, the Changing Children's Services Fund was used in 1996 to set up *Spectrum* – a multiagency intervention team providing support for preschool children and their families from the point of concern that autism may explain the child's difficulties (not from the time of diagnosis, which may be much later). The Scottish Centre for Autism early intervention programme published evidence that 10 h of intervention was as effective as some of the 40 h a week private intervention programs being advertised in the USA. Achievable and sustainable models of early intervention were being developed by statutory services.

Interventions and teaching methods in use internationally began to be adopted locally such as use of TEACCH (Mesibov et al. 2004), the Hanen parent programmes (Sussman 2006, 2012; Carter et al. 2011), both of which emerged in the 1970s in North America and Canada but came to Scotland in the early 1990s. While intensive interaction (Nind and Hewett 2012) and Makaton signing (Mirenda and Teresa 2009) were widely used in Scotland with children with learning or language difficulties, there was minimal use of either approach or of visual and symbol supports for children with autism. The advent of technology (e.g., laminators, computer access to symbols) supported the developing use of visual supports for children with autism (Howlin

et al. 2007; PECS UK 2016) and growing awareness that the environment was crucial in supporting children with autism. The Hanen programme advocated the importance of the impact of parents and carers in using everyday interactions to enhance development in children with communication impairments and then specifically for those with autism (Carter et al. 2011).

Since 2000, there has been a further shift and growth in educational practice and thinking with a move towards increased inclusion of pupils with autism and other additional needs in local schools, with "the presumption of mainstream" being adopted (Standards in Scotland's Schools Act, 2000) and the requirement of schools to adapt to the needs of all children (Education (Additional Support for Learning) Acts 2004 and 2009; The Equality Act 2010). Practice guidance for practitioners became more widely available, for example, due to the Autism Toolbox (2016). While this process engenders new challenges, the context in Scotland is increasingly positive and statutory services are working in partnership with parent groups and the third sector, researchers and professionals, to work towards improving recognition and models of service provision across the country.

Overview of Assessment and Supportive Intervention and Social Policy/Training Initiatives

Scotland has produced several centers of excellence in terms of educational and clinical practice in autism over the last 50 years, which have been the subject of international attention. This productivity stems in part from the strong tradition of relatively well-resourced, public-funded health and education services in Scotland. However, third sector/charitable organizations have also pioneered service development, often leading the way when public services have failed to keep up with emerging needs. Thus the Steiner movement in Camphill (Aberdeen) and Ochil Tower School (Auchterarder), the New School at Struan (Scottish Society for Autism), and the Scottish

Centre for Autism have all produced in-house approaches to autism intervention and support which have been adopted and adapted by services at home and abroad.

The work of the Scottish Government's Autism Reference Group (ARG) (2002 to date, now called the Scottish Autism Strategy Governance Group) has helped to frame many concepts in the area of autism assessment (The Quality Diagnostic Standard) and educational support and intervention (The Autism Toolbox) (2016) which have begun to generate a standardized quality and approach to services nationally, across disciplines and agencies. The Scottish Government's work on autism has been formulated within a 10-year Autism Strategy, funded by £14.5 million (2016), meaning that the Scottish Government is, arguably, one of the leading national legislatures in terms of developing autism services.

Autism assessment has gradually developed a standardized approach throughout the country and its improvement has, arguably, been one of Scotland's key successes in comparison with other nations. NHS Education for Scotland (NES) funded the development of an ADOS Training network from the mid 2000s onwards, which has steadily increased the numbers of professionals from all agencies offering this skill. Training in other diagnostic instruments such as DISCO and 3di has been supported by the Scottish Government, via the ARG. Thus autism assessment services are now in a much healthier state than they were in the early 1990s. However, there are still major challenges. Autism assessment waiting lists for children are growing, capacity is insufficient, and services for adults (especially those for adults without a learning disability) are nonexistent in some parts of Scotland. Recently, the Scottish Government funded the Autism ACHIEVE Alliance (AAA) to survey the state of autism assessment services across the age range, across the country and these findings have been published as an Executive Summary report (Autism Spectrum Disorders – Waiting For Assessment & Executive Summary 2014) as well as peer reviewed publications (Mckenzie et al. 2015; Rutherford et al. 2016a, b). This is the first time any national government has

attempted to establish the state of a country's autism assessment services and the AAA findings will provide a framework for action, in terms of how to improve the situation, over the next decade.

Overview of Research Directions

Several pioneers of early autism research have been based in Scotland, such as Stone, Wolff, and Trevarthen. The SIGN guideline helped to demonstrate key gaps in the autism evidence base affecting Scotland and many other countries (Guideline 2016). However, mainstream psychiatric research in Scotland has only recently begun to take an interest in autism, perhaps reflecting the relatively weak base of research into child and adolescent mental health in Scotland, compared to the historical emphasis on schizophrenia and other conditions which mainly affect adults. The work of the Scottish Government and other agencies, over the last decade, has helped to galvanize autism research and bring local researchers into contact with international pioneers, to hopefully stimulate and assist a new generation of autism researchers.

Definition

This entry focuses on screening instruments for autism spectrum disorders (ASD). By screening instruments, we are referring to two different purposes of instruments: Level 1 (Universal Screening or General Population Screening) and Level 2 (often tailored to other instruments for ASD screening in high risk cohorts, such as clinical samples). Level 1 screening instruments are often designed as parental questionnaires, while Level 2 screening instruments are typically designed to probe for ASD specific symptoms utilizing parent-endorsement and/or observations by a clinician. In terms of Level 1 screening instruments, the Modified Checklist for Autism in Toddlers (M-CHAT)(R/F) (Ibanez et al. 2014; Robins et al. 2001, 2014) is the most widely used instrument for ASD-specific screening. The M-CHAT is designed to be completed in a primary care provider setting (Robins et al.

2001). Among Level 2 screening instruments, the most frequently used examinations/assessments are the Childhood Autism Rating Scale (CARS/CARS2) (Schopler and Reichler 1988; Schopler et al. 1980), the Social Communicative Questionnaire (SCQ) (Rutter et al. 2003), and the Screening Tool for Autism in Toddlers (STAT) (Stone et al. 2004). These screening instruments are tailored for identification of ASD, usually primarily in toddlers and young children. Both Level 1 and Level 2 instruments aim to identify symptoms within the categories of symptom descriptions (social, communication, and RRB), more specifically behaviors related to sharing, perspective-taking, joint attention, language development, and unusual/encompassing behaviors and interests.

To increase cost efficiency and decrease the threshold for utilization, these instruments are most often designed as brief parent endorsed questionnaires that can be completed out swiftly in, e.g., the waiting room of a pediatrician. The ideal aim of screening instruments is to identify as many (if not all) of the children with the condition that are in the population screened.

Background

Over the past 30 years an increasing amount of studies on early identification of ASD have emerged. A wide range of screening instruments have been developed and further modified as the criteria for ASD have changed across diagnostic manuals (American Psychiatric Association 2000, 2013; Banach et al. 2009; World Health Organization 1992). Baron-Cohen et al. (1992) conducted one of the first studies to utilize an ASD-specific screening instrument, which assessed the performance of the Checklist for Autism in Toddlers (CHAT). The checklist was a nine-item parent endorsed list of behaviors and in addition to these items, it included three observational-based items intended for the general practitioner to complete during the health visit (Baron-Cohen et al. 1992). The result of screening approximately 16,000 18 months old

children was that almost all of the screen positive children were diagnosed with ASD when assessed. The screening criteria was defined as failing the three predefined key items of the nine endorsed by parents and confirmed through the general practitioner's observations. The researchers also conducted a 6-year follow-up study of the same population that was screened at 18 months. The 6-year follow-up revealed that a large proportion of the children with an ASD diagnosis at follow-up were not identified by CHAT at 18 months at the health visit (Baird et al. 2000). These were false negative cases on the CHAT.

Some of the false negatives in this study may have been due to the widening of diagnostic criteria for the various autism spectrum diagnoses that occurred during the 1990s. In 2001, Robins and Colleagues (Robins et al. 2001) published a validation study on a modified version of the CHAT, including a range of new items to the screener. The aim of the Modified Checklist for Autism in Toddlers (M-CHAT) and arguments for including a range of new items was to identify the broader autism spectrum now included in both the ICD-10 (World Health Organization 1992) and the DSM-IV-TR (American Psychiatric Association 2000). None of the studies conducted utilizing the M-CHAT during the early 2000s included diagnostic assessment or prospective follow-up of all screen negative cases (Kleinman et al. 2008; Robins et al. 2001). Many of the studies using M-CHAT reported excellent psychometric properties with both high sensitivity and specificity. This contributed to M-CHAT as the recommended (preferred) screening instruments in most parts of the world, and it has been validated in various languages and cultures (Robins 2018). The M-CHAT has received some criticism for the high rates of false positives, identifying children as probable ASD in 10% of the unselected population without receiving the diagnosis upon assessment. This resulted in the development of the M-CHAT R/F (Robins et al. 2014) with the explicit goal of reducing the number of false positives. However, the instrument has yet to be examined in terms of also reducing the number of false negatives.

Current Knowledge

In recent years, the recommendation relating to Level 1 screening (i.e., universal or general population screening) have ranged from recommending it (Committee on Practice and Ambulatory Medicine, Bright Futures Periodicity Schedule Workgroup 2016; McPheeters et al. 2016) to not recommend using it in the general population due to lack of evidence for the efficacy of screening entire populations (Siu et al. 2016; UK National Screening Committee 2012). In terms of the latter, researchers have not presented evidence whether existing screening instruments are able to detect ASD across the whole spectrum of symptom patterns in children who develop ASD even though it seems like most instruments pick up on the most severe children (Beuker et al. 2014; Kleinman et al. 2008; Robins et al. 2001; Stenberg et al. 2014; Øien et al. 2018). Another critical issue of screening in the general populations is the costs, both in terms of resources used to assess screen positive children and also in terms of concerns and unnecessary worries in parents of false positive children. Screening in general populations comes with a high price as the high number of false positives most probably would prolong the time taken before the assessment of children who truly require evaluation for ASD and can result in increased healthcare cost (Yuen et al. 2018).

The American Academy of Pediatrics recommends universal screening for ASD for all children at 18- and 24-month well-visits (Committee on Practice and Ambulatory Medicine, Bright Futures Periodicity Schedule Workgroup 2016; Zwaigenbaum et al. 2015). However, the lack of studies utilizing prospective general population data with long-term follow-up demonstrates a knowledge gap in the literature. As few studies have diagnostically assessed the children who were screened – either they were true positive, false positive, true negative, or false negative – the true performance of a given instrument cannot be calculated from the majority of screening studies. There are however some exceptions: the CHAT study utilizing a 6-year follow-up (Baird et al. 2000; Baron-Cohen et al. 2000) and

Stenberg and colleagues study utilizing a prospective pregnancy cohort in the Norwegian Mother and Child Study (with yearly patient registry linkage as children grow older) (Stenberg et al. 2014). The lack of prospective studies with follow-up limits our current understanding of how well a screening instrument performs in identifying the broad spectrum of children with ASD and to what extent only a subset of children with ASD are captured.

Many of the different screening instruments used have faced criticism due to its low specificity by capturing many children with other types of developmental problems as well as children with severe intellectual impairment, but with no ASD (Chlebowski et al. 2013; Pandey et al. 2008). In addition, research in general population samples show that screening at 18 months misses a large proportion of children who later were identified with ASD (false negatives), even when the parents, at the same time, rate their children with atypicalities on other instruments (Øien et al. 2018).

Future Directions

This entry has highlighted that screening for ASD in general populations is difficult, while use of screening instruments in high-risk samples potentially benefit children not only with ASD, but also children on the developmental path to other diagnosis. Changes to cut-offs would not improve the rate of false negatives as they most often show no actionable concern on these instruments (screen negatives with very low scores). This should encourage clinicians to not rely solely on the instrument, but utilize parental concern, surveillance of developmental milestones, and provide good clinical judgment (Øien et al. 2018).

More problematic is the fact that some children on the path of developing ASD most probably do not show the range of ASD-like symptoms that, to our current knowledge, should be indicators for raising actionable concern at 18 and/or 24 months of age. While this indicates that we, using existing screening instrument, will not be able to identify all children with ASD at 18 and/or 24 months of

age, this should still be the goal for future screening studies. A renewed focus is needed on both improving already developed screening instruments and, foremost, providing more research on how to capture children with milder general developmental delay, possibly with more spared functions linked to language and mental abilities. We know far less of the symptom patterns in these children when they were 18 or 24 months of age. It is important to take other factors into account as well in future research. The wording of items can influence how they are rated, and more research is needed focusing how this and the grading of response options on individual items influences parents/professionals rating.

When developing new screening instruments aiming to identify children also from the broader autism spectrum, it is necessary that the field looks toward prospective general population studies such as the Norwegian MoBa. Such samples will allow researchers to examine trajectories of development and behavior even when diagnosed later in life. Such studies could potentially contribute to our understanding of symptoms specific to subgroups of children, or even symptoms that we do not usually consider core symptoms. This approach should ultimately lead to a better understanding of what phenomena to probe for in the development or modification of screening instruments.

The heterogeneity in ASD increased with the introduction of the DSM-IV(-TR) (American Psychiatric Association 2000) and ICD-10 (World Health Organization 1992), as the criteria also increased the number of children within the normal range IQ and complex language. Due to the heterogeneous nature of ASD, designing brief screening instruments to detect the broader autism spectrum is associated with great difficulties. Heterogeneity over time and patterns of symptom onset as well as different developmental pathways contributes to the complexities of identifying children using only one screening instrument at a given age. Designing a flawless instrument might be impossible, but improvements in the design or modification of instruments should be a focus for future studies. It might be questioned whether a child is missed by current screening

instruments due to the fact that it does not show the amount of symptoms to raise concern at the time of screening, or if current screening instruments do not contain the relevant behavioral markers to capture children across the whole spectrum and are therefore not able to identify all children with ASD due to the heterogeneity.

Definition

Autism screening is the process of administering a brief assessment to determine the level of risk for

autism. This is usually done by giving parents a brief questionnaire or checklist about their child's development, including social, language, motor, and cognitive development, but can also be done by direct clinical observation. If concerns about a child's development arise from the screening instrument, the child is referred for a more in-depth, diagnostic, and developmental evaluation.

Historical Background

Autism spectrum disorders (ASDs) are disorders of development; the Centers for Disease Control reported prevalence rates as 1 in 59 in 2014 (Baio et al. 2018). Evidence of neurobiological abnormalities in the first year of life (Courchesne 2004) and retrospective evaluation of infant behavior (Baranek 1999; Osterling and Dawson 1994) suggest that symptoms of ASD may be present by 12 months. Parents first report concerns around 17–18 months on average, although recent data suggest that parents first express concerns around 14–15 months, with some stating concerns before 11 months (Chawarska et al. 2007). Despite parents' early concerns, most children are not diagnosed with ASD until age 4 or even later, especially children of urban and/or low socioeconomic status (Baio et al. 2018; Earls and Hay 2006; Fombonne et al. 2001; Howlin and Asgharian 1999; Mandell et al. 2002; Pinto-Martin et al. 2005; Tonge et al. 2006; Wiggins et al. 2006; Williams and Brayne 2006; Zwaigenbaum et al. 2007). Furthermore, diagnoses of ASD have been demonstrated to be stable and reliable in children as young as 14 months of age (Pierce et al. 2019), even in children with significantly delayed language and cognitive abilities (Hinnebusch et al. 2017). Published guidelines (Filipek et al. 2000; Glascoe 2005; Gray et al. 2006; Johnson and Myers 2007) report that the positive effects of early diagnosis far outweigh the negative effects and that families express the desire to be informed as early as possible. Early identification of children with autism enables families to access early intervention services, which have been shown to lead to the best outcomes

when accessed early in life (MacDonald et al. 2014; Rogers et al. 2014). Standardized universal screening reduces the delay in diagnosis experienced by low-resource and minority families (Herlihy et al. 2014). Screening instruments that alert doctors to the possibility of ASD are important and necessary and have a tremendous impact on public health and the welfare of affected children and their families. Pediatric screening is often the only evaluation children receive until they begin preschool or kindergarten (Glascoe 2005). Therefore, what is needed is a brief, but relatively sensitive, screening instrument for use in physicians' offices that indicate a need for further evaluation in children with early signs of autism. There is clear evidence that early detection of and intervention for ASDs can lead to substantially better prognosis; thus, the American Academy of Pediatrics currently recommends that all children be screened for autism at their 18- and 24-month well-child visits and that children who "fail" screening be referred for a diagnostic evaluation (Lipkin et al. 2020). Here we describe some commonly used screening measures; a review of screening tools available for use in low- and middle-income countries can be found in Marlow et al. (2019).

While the majority of the screening instruments described here are designed for infants and toddlers, several are also applicable for older children and adults. Recent work reporting on children who are not detected by early developmental screeners but are later diagnosed with autism has concluded that use of multiple screening tools reduces false-negative risk (Beacham et al. 2018) and screening at repeated time points (e.g., 18 months and 24 months) is beneficial (Dai et al. 2019; Øien et al. 2018; Robins 2019). For screening of older children and adults, we refer the reader to the following reviews: Baghdadli et al. (2017) and Hirota et al. (2018).

Current Knowledge

Autism screeners fall into two different levels. Level 1 screening instruments are broad-based and used to identify children at risk for ASDs in

the general population. Level 2 screening instruments are more specific tools used to screen children who are at increased risk for ASDs (e.g., children with previous developmental concerns, younger siblings of children with ASDs). Level 1 screening instruments are designed to be implemented by general providers, without specialized knowledge about ASDs. Typically, pediatricians conduct screening with level 1 instruments during well-child visits. Therefore, these screening instruments must be brief and easy to administer. Level 2 screening instruments generally take longer to complete and are typically utilized by practitioners with specific training on ASDs. Level 2 screening instruments include parent report and sometimes include direct observation of the child. Some screening measures have both level 1 and level 2 components and thus can be used in a variety of settings. When evaluating screening instruments, two constructs are important: sensitivity and specificity. Sensitivity is the proportion of children correctly identified by the screening instrument as having an ASD, while specificity is the proportion of children correctly identified by the screening instrument as not having an ASD. High sensitivity is important for level 1 screening instruments in order to maximally identify all children at risk for an ASD. Specificity may be less important for level 1 screening instruments because children who show concerns based on the screening instrument are likely to benefit from evaluation and intervention whether or not they have an ASD. However, for level 2 screening instruments, specificity is more highly valued since diagnosis becomes important, and distinguishing between ASD and other developmental disabilities is necessary. In addition to sensitivity and specificity, many instruments report their positive predictive value (PPVs). This figure is the proportion of children screening positive who turn out to be true cases. This figure is very sensitive to base rates. Conditions with low base rates tend to have low PPVs. In addition, there is always a trade-off between sensitivity and PPV; instruments that pick up most cases (high sensitivity) also tend to pick up more false-positive cases, resulting in lower PPVs. Because of the trade-off with

sensitivity, and because of the variation in PPV with base rate, PPV is not always reported. A recent meta-analysis of screening tools in toddlers (Sánchez-García et al. 2019) indicated that screening tools in toddlers are effective and accurate, and the authors include several recommendations for future screening studies.

Broad Developmental Screening Tools

Broad developmental screening tools are designed to assess risk for any developmental disorder and are not specifically designed to assess risk for ASDs. A thorough examination of all such measures is beyond the scope of this entry (see Glascoe 2000 or Macy 2012 for a review); however, three common broad developmental screening tools are discussed, all of which are recommended by the American Academy of Pediatrics (AAP) Screening Tool Finder. The Parents' Evaluation of Developmental Status (PEDS) (Glascoe 2001) is a screening instrument designed for use in children between birth and 8 years of age. The PEDS contains ten items that assess parent concern in developmental domains such as fine and gross motor skills, receptive and expressive language, and self-help skills. Based on the reported parental concerns, the child is classified as being at low, moderate, or high risk for developmental issues. The PEDS showed sensitivity ranging from 0.74 to 0.79 and specificity of 0.70 to 0.80 across a broad age range. The Ages and Stages Questionnaires, Third Edition (ASQ-3; Squires et al. 2009), is a screening instrument designed for use in children from 1 to 66 months. There are 21 different forms specific to the skills expected of the various age levels assessed. There are 30 items divided into 5 areas: communication, gross motor, fine motor, problem solving, and personal social. The ASQ-3 showed sensitivity of at least 0.86, and specificity has been measured at 0.85 for all age groups. There are questions on behavior and communication within this third edition that help identify parent concerns that may be related to ASD. Emerging data on whether the PEDS or the ASQ-3 is targeted enough for the identification

of children at risk for an ASD suggest that they may be useful as first-level screeners if fairly low thresholds are used, but current findings are limited and require further study (Wiggins et al. 2014; Hardy et al. 2015). A third screening measure used to identify a range of developmental concerns is the Survey of Wellbeing of Young Children (SWYC), designed for children under age 5½ years. There are 12 separate versions for children of different ages (designed to be administered at each well-child checkup until age 5 years). Autism-specific scales are included for children 16–36 months of age (Perrin et al. 2016). Early estimates of validity suggest the SWYC is comparable to other developmental screening tools, and the authors are continuing to evaluate validity compared to standardized developmental testing.

Autism-Specific Screening Tools

Checklist for Autism in Toddlers (CHAT; Level 1)

Developed in the United Kingdom (UK), the CHAT (Baron-Cohen et al. 1992, 1996, 2000) is a screening tool developed for pediatricians to use at the 18-month checkup for children. The CHAT consists of nine yes/no questions to be answered by the child's parent. These questions ask if the child exhibits specific behaviors, including social play, social interest in other children, pretend play, joint attention, pointing to ask for something, pointing to indicate interest in something, rough and tumble play, motor development, and functional play. The CHAT also includes observations of five brief interactions between the child and the examiner, which enable the clinician to compare the child's actual behavior with the parental reports. The specificity of the CHAT is excellent; however, the sensitivity is quite low (0.20–0.38 depending on criteria used).

Early Screening of Autistic Traits Questionnaire (ESAT; Level 1)

The ESAT (Dietz et al. 2006; Swinkels et al. 2006) screening tool consists of 14 yes/no items completed by parents of children age

0–36 months (although it has only been empirically demonstrated in children age 8–20 months). It covers the domains of pretend play, joint attention, interest in others, eye contact, verbal and nonverbal communication, stereotypes, preoccupations, reaction to sensory stimuli, emotional reaction, and social interaction. Children failing three or more items are considered at risk for ASD. Early estimates suggest that the ESAT's sensitivity is greater than 0.9, but specificity is considerably lower. However, these values were derived from a sample that was pre-screened and thus should be interpreted with caution, as they are not derived from the general population (Towle and Patrick 2016). Additionally, the ESAT has not been demonstrated in a prospective sample.

Communication and Symbolic Behavior Scales Developmental Profile Infant-Toddler Checklist (CSBS-DP-IT Checklist; Level 1)

The CSBS-DP-IT Checklist (Wetherby et al. 2002) is a 24-item parent-report questionnaire shown to have both high sensitivity and specificity. There are three subdomains: social and emotional communication, receptive and expressive speech, and symbolic behavior. Because the CSBS-DP-IT Checklist was designed to detect children with a variety of communication delays, it tends to be sensitive to autism as well. For clinical purposes, it has the potential to identify a wide range of children who may benefit from early treatment. A study by Pierce et al. (2011) reported a PPV of 0.75 for ASD and other developmental disorders compared to typical development when used in pediatric well-child visits at 12 months of age, but pediatricians were free to override screening results and fail to refer children for evaluation. Twenty percent of screen positives were found to have an ASD, 55% another developmental disorder, and 25% false positives (Pierce et al. 2011). While sensitivity for ASD in particular is unknown at this age, and it remains probable that a 12-month-old screening will not pick up the majority of ASD cases, it is promising as a general screening at 12 months, which would then need to be followed by additional ASD-specific screening.

Developmental Check-In (DCI; Level 1)

The DCI is a novel screening tool designed for use in underserved populations for whom literacy limitations may interfere with their engagement with other screening strategies (Janvier et al. 2019). The DCI presents 28 social, language, and developmental red flags in the form of images with very limited use of text. Caregivers responded to each yes/no item based on the child's behavior. Cutoffs were determined empirically for various age and gender groups; in the total sample, sensitivity was 0.66 and specificity was 0.76. Although there is currently limited empirical support for the DCI, it may be particularly useful in certain underserved groups, including families with limited education, and those whose English proficiency is limited.

Pervasive Developmental Disorders Screening Test, Second Edition (PDDST-II; Levels 1 and 2)

The PDDST-II (Siegel 2004) consists of three stages designed to be administered in different settings by clinicians of increasing knowledge about ASDs. The first stage consists of 22 yes/no items and is intended for use by pediatricians in primary care settings for children 12–48 months. Further evaluation is recommended for children with five or more items answered as “yes.” According to the author, using these criteria, sensitivity is 0.92 and specificity is 0.91 in an “at-risk” sample (Siegel 2004). The second stage of the PDDST-II is a 14-item measure that is intended for use in developmental clinics. The cutoff is still five items in the second stage, with a sensitivity of 0.73 and specificity of 0.49. The third and final stage consists of 12 items and is intended for use in autism clinics. The cutoff for this stage is a score of 8, with sensitivity of 0.58 and specificity of 0.60. Unfortunately, sensitivity and specificity have not yet been reported for the PDDST-II in a large population-based sample.

Modified Checklist for Autism in Toddlers-Revised with Follow-Up (M-CHAT-R/F; Levels 1 and 2)

One of the most commonly used autism screening measures in the United States is the M-CHAT-R/F (Robins et al. 2014), which is nationally

recommended by the AAP. The M-CHAT-R/F consists of two stages of screening. The first stage is a 20-item yes or no parent questionnaire that screens for signs of an ASD in children aged 16–30 months. This is a level 1 screening instrument and is widely used by pediatric offices across the nation and internationally; the M-CHAT has been translated into more than 50 languages. The M-CHAT-R is scored “Low Risk,” if parents respond in a way that indicates risk for ASD on 0–2 items, whereas parent responses are scored “Medium Risk” if they indicate risk for ASD on 3–8 items, or “High Risk” if parent responses indicate risk for ASD on 8–20 items. High-risk children can be referred immediately for evaluation. For medium-risk children, a second stage of screening is a follow-up interview (which can be done on the phone or in person). The interview is completed by following a script, although it involves some clinical judgment. If a child continues to indicate risk on two or more items on the M-CHAT-R/F, it is strongly recommended that the child be referred for early intervention and diagnostic assessment. While the M-CHAT-R/F detects ASD at a higher rate compared to the M-CHAT while also reducing the number of children needing follow-up, additional studies are still under way to get a firmer idea of sensitivity and specificity for this revised screening instrument.

Social Responsiveness Scale: Second Edition (SRS-2; Level 2)

The SRS-2 (Constantino and Gruber 2012) is a 65-item rating scale that measures the severity of autism spectrum symptoms as they occur in natural social settings. The SRS-2 is completed by a parent or teacher in just 15–20 min and provides a clear picture of a child's social impairments, assessing social awareness, social information processing, capacity for reciprocal social communication, social anxiety/avoidance, and autistic preoccupations and traits. It is appropriate for use with individuals aged 2.5 through adulthood. The SRS-2 can be used as a level 2 screener in clinical or educational settings, an aid to clinical diagnosis, or a measure of response to intervention. SRS-2 scores are particularly helpful in identifying the severity of social impairment based on

five treatment subscales: social awareness, social cognition, social communication, social motivation, and restricted interests and repetitive behavior. Raw scores are converted to T-scores for gender and respondent; a total T-score of 60–75 is considered a mild to moderate indication of deficient reciprocal social behavior reflecting autism spectrum disorder, while a T-score of 76 or higher is considered severe and strongly associated with a clinical diagnosis of autism spectrum disorder. For a cutoff raw score of 80, sensitivity is reported as 0.78 and specificity as 0.94 in the SRS-2 manual.

Screening Tool for Autism in 2-Year-Olds (STAT; Level 2)

The STAT (Stone et al. 2000) is an interactive measure that is designed to differentiate between autism and other developmental disorders and is therefore intended for children 24–35 months old already identified as at risk for an ASD, although it has been shown to be useful in samples as young as 14 months of age (Stone et al. 2008). The STAT is administered within the context of play and takes about 20 min to complete. The STAT consists of 12 items that were derived from three measures: the Play Assessment Scale (Fewell 1991), the Prelinguistic Communication Assessment (Stone et al. 1997b), and the Motor Imitation Scale (Stone et al. 1997a). Items assess behaviors in four social-communicative domains that do not require language comprehension: play, requesting, directing attention, and motor imitation. Sensitivity of the STAT is estimated to be 0.92 and specificity is 0.85 (Stone et al. 2004).

Childhood Autism Rating Scale: Second Edition (CARS2; Level 2)

The CARS2 (Schopler et al. 2010) is a behavioral rating scale designed for the identification of autism in children. There are two forms, the Standard Version (CARS2-ST) and High-Functioning version (CARS2-HF); each form consists of 15 items, each rated on a scale of 1–4. The CARS2 is based on a trained rater's clinical judgment of observed behavior and parent report.

A total score is calculated by adding the scores of the individual items. Scores of 30–36.5 on the ST form and 28–33.5 on the HF form suggest mild to moderate autism, and scores of 37–60 on the CARS2-ST form and 34–60 on the CARS2-HF form indicate severe autism. Chlebowski et al. (2010) found that a score of 25.5–30 is consistent with PDD-NOS. The CARS2-ST and CARS2-HF forms appear to be both sensitive and specific to behavioral problems associated with autism.

Gilliam Autism Rating Scale: Third Edition (GARS-3; Level 2)

The GARS-3 (Gilliam 2014) is a symptom severity behavioral checklist that assists teachers, parents, and clinicians in identifying and diagnosing autism in individuals ages 3 through 22. The 56 items on the GARS-3 are based on the definitions of autism adopted by the American Psychological Association and the 2013 *Diagnostic and Statistical Manual of Mental Disorders: Fifth Edition* (DSM-V) and are grouped into 6 subscales: restrictive/repetitive behaviors, social interaction, social communication, emotional responses, cognitive style, and maladaptive speech. Raw scores combine to give standard scores, percentile ranks, severity level, and binary probability of autism called the autism quotient, with higher scores reflecting greater severity of impairment. Using the new cutoff scores, the estimated diagnostic sensitivity and specificity of the GARS-3 are 0.97.

Social Communication Questionnaire (SCQ; Level 2)

The SCQ (Berument et al. 1999) is a 40-item screening questionnaire designed for parents to complete about their child aged 4–40 years, with a mental age of at least 2 years. There are both current and lifetime versions available to detect signs of an ASD in children. A cutoff score of 22 is used to differentiate autism from other ASDs, and a cutoff score of 15 is used to differentiate ASDs from other developmental disorders. Sensitivity of the SCQ is 0.85 and specificity is 0.75.

Future Directions

A controversy about the advisability of universal early ASD screening has been raised by the United States Preventive Services Task Force. They concluded that early screening was sufficiently accurate and that early intervention had demonstrated efficacy in improving outcomes, but concluded that a randomized controlled trial was needed to assess outcomes for children who participated in early universal screening versus those who did not (Siu and US Preventive Services Task Force 2016). This position has been rebutted by many organizations and research teams (Robins et al. 2016; Fein and Baby Sibs Research Consortium 2016; Fein et al. 2017).

Continued research to refine the screening instruments for increased accuracy, including better sensitivity and specificity, in identification of children at risk for ASDs is warranted. Furthermore, additional research regarding the utility of broad developmental screening in detecting children at risk for ASDs is necessary to determine whether an autism-specific screening instrument is necessary. Finally, future research will help clarify the most appropriate time points for autism screening.

Screening of Autism Spectrum Disorders in Older Adults

S. M. J. Heijnen-Kohl

Mondriaan Geriatric Mental Health Care,
Heerlen-Maastricht, The Netherlands

Definition

HAP: The hetero-anamnestic personality questionnaire can be used as a screener for ASD features in older adults.

People on the autism spectrum experience more psychiatric problems than neurotypical people. When they turn to mental health care facilities for help, it is important to detect (features of) an autism spectrum disorder (ASD) to provide suitable care. In the field of elderly care or geriatric psychiatry however, there is a lack of knowledge about how to detect and diagnose ASD and how to care for autistic older adults. Detecting ASD (features) in an early stage of diagnosis and treatment is of great benefit to autistic older adults and their families. It is important that they get appropriate care that takes into account age-related factors. However, there is a lack of research on the topic, even though the subject is getting more attention and there is gradually more awareness and understanding about ASD and aging.

ASD in older adults can easily be overlooked. First, older adults and their families often seek help because of other complaints, such as depression or anxiety. Second, the features of ASD might be different in older adults, for example, as a result of a lifetime of social camouflaging. It

can take long before a diagnosis of ASD is confirmed and appropriate care is provided.

To help clinicians detect these features and be able to screen for ASD in older adults, a study was conducted with the Hetero-Anamnestic Personality Questionnaire (HAP): an informant-based personality questionnaire, developed and validated for older adults. This measure has several advantages. First, it can be administered as a general screener. It is aimed at personality traits, and research has shown that autistic people score differently on certain scales of various personality questionnaires. Even if a clinician initially does not consider ASD, the results can still indicate in that direction. Second, because it is informant based, it is not dependent on co-occurring psychiatric or cognitive impairments of the older adult and can therefore be administered at the beginning of diagnosis and treatment.

A group of older adults (age > 60) with ($N = 40$) and without ($N = 43$) ASD, all receiving psychiatric or psychological care because of various psychiatric or cognitive impairments (with the exception of personality disorders), were compared on the scores of the HAP. The ASD group had significantly higher scores, with large effect sizes, on the HAP scales: “Socially avoidant behavior,” “Rigid behavior,” and “Unpredictable and impulsive behavior.” These scales were also capable of discriminating between persons with and without ASD. Cutoff points were determined at 5 for “Socially avoidant behavior” and 4 for “Rigid behavior” and “Unpredictable and impulsive behavior.”

Further research is needed to determine whether the HAP can also discriminate between autistic people and people with a personality disorder. Because the study was executed in the Netherlands, in a small population (albeit with sufficient statistical power for this study), with no additional data on severity of ASD or severity of co-occurring psychiatric symptoms, further research is also needed to determine whether these results are replicable and to obtain more knowledge on the subject.

Nevertheless, the HAP turns out to have feasibility in care settings and mental health institutions as a screener for ASD in older adults, even if there are co-occurring conditions. It can be

administered at the beginning of a diagnostic process when ASD is not even considered as a diagnosis. This can save time in starting up appropriate care for older autistic adults and their families.

Screening Test for Auditory Processing Disorders

Jennifer McCullagh

Department of Communication Disorders,
Southern Connecticut State University, New
Haven, CT, USA

Synonyms

SCAN-A (adults); SCAN-C (children)

Description

The Screening Test for Auditory Disorders (SCAN) is a screening tool used to determine if a child (or adult) should be evaluated for central auditory processing (CAP) disorders. The SCAN-C is a CAP screening instrument for children (Keith 1986, 2000a, b), while the SCAN-A is used for adolescents and adults (Keith 1994). The revised SCAN-C was designed for children from 5 to 11 years of age and consists of four subtests: Filtered Words, Auditory Figure Ground (speech-in-noise), Competing Words, and Competing Sentences (Keith 2000a, b). The Filtered Words subtest consists of 1,000-Hz low-pass filtered monosyllabic words with a filter roll-off of 32 dB/octave. The listener must repeat the word she/he perceives. The Auditory Figure Ground subtest consists of monosyllabic words recorded at +8 signal-to-noise ratio with a multi-talker babble background. The listener must repeat the stimulus words in the presence of the background noise. The Competing Words subtest consists of monosyllabic word pairs presented to both ears (dichotically) with simultaneous onset times (Keith et al. 1989). As a directed listening task, the listener is first asked to repeat both words that are perceived, repeating the word heard in the right ear first. Then a second test list is given and the listener must repeat both words that are perceived, repeating the word heard in the left ear first. The Competing Sentences subtest consists of sentence pairs that are unrelated in topic which are presented to both ears (dichotically) with

simultaneous onset times (Keith 2000b). The listener is asked to repeat only the sentence heard in the right ear. Then a second test list is given and the listener is asked to repeat only the sentence heard in the left ear. These subtests are pre-recorded and can be administered under headphones in a quiet room. The raw scores on each of the SCAN subtests are converted to standard scores, percentile ranks, and confidence intervals. The screening is easy to administer and score. Total test time is approximately 20 min.

Historical Background

The SCAN was developed to be a screening test for CAP in children and was first introduced in 1986. The goal of this screening test was to help assess auditory maturation and identify children who may benefit from more involved CAP testing and specific auditory rehabilitation. The original SCAN-C was developed for children between the ages of 3 and 11 years and included three subtests: Filtered Words, Auditory Figure Ground, and Competing Words. Keith et al. (1989) demonstrated that the SCAN Competing Words subtest was highly correlated with other tests of dichotic listening (Staggered Spondaic Words (SSW) and Competing Sentences Test (CST)). These researchers also demonstrated that language abilities may affect performance on the SCAN. Subsequent research indicated that the original SCAN-C test-retest reliability may have been poor, with children performing better on the second administration of the screener than the first administration (Amos and Humes 1998). In addition, researchers showed that children performed more poorly in a quiet room compared to an audiologic booth (Emerson et al. 1997). These, along with other factors, led to the development of the revised SCAN-C which included an additional subtest (Competing Sentences), new test instructions to make them easier for young children to understand, test materials recorded on compact discs rather than audiocassettes, and fewer word pairs for the Competing Words subtest to make the

test more efficient. Research completed by Keith (2000b) indicated improved test-retest reliability and no significant differences in performance between test environments (quiet room vs. audiologic booth).

Psychometric Data

Normative data exist on a wide age range (5–11 years) with a total sample size of 650 children. Normative data indicate a systematic improvement in performance with increase in age. Test-retest reliability was high for children between the ages of 5 and 7 years. Children included in the normative sample were all able to take the test in English without test modifications, had normal and symmetric hearing from the octave frequencies between 500 and 4,000 Hz, and had intelligible speech with few articulation errors. Children were excluded from the standardization sample if they were receiving special education services or services related to gifted and talented programs (Keith 2000b).

Like other tests of central auditory processing, early research completed on the SCAN included children who spoke English as their primary language, were in regular education classrooms (without special education services), and demonstrated normal hearing and normal middle ear function (Amos and Humes 1998; Emerson et al. 1997; Keith 2000b; Keith et al. 1989). Furthermore, it should be noted that researchers have found that children with language problems might score poorly on the SCAN (Keith et al. 1989). This is likely due to the fact that the test stimuli on the SCAN have a high linguistic load.

Clinical Uses

The SCAN-C is often used in school systems as well as audiological practices to determine if a more thorough CAP evaluation is warranted. It is often administered by a speech-language pathologist in a quiet room in the school setting,

and referrals are made to audiologists for further CAP testing as necessary. Clinically, the person administering the SCAN should take into consideration the cognitive, hearing, speech, and language abilities of the individual being tested as these factors may affect screening outcomes. Thus, the SCAN-C is not typically administered to children with autism, and performance on this screener should be interpreted with caution in this population.

Screening Tool for Autism in Toddlers

► Screening Tool for Autism in Two-Year-Olds (STAT)

Screening Tool for Autism in Two-Year-Olds (STAT)

Wendy L. Stone

Department of Psychology, UW READi Lab,
University of Washington, Seattle, WA, USA

Synonyms

Screening tool for autism in toddlers; STAT

Description

The STAT is an interactive, play-based screening instrument for autism that contains 12 items tapping the core deficit areas of socialization and communication. Items are organized into four domains: play (two items), requesting (two items), directing attention (four items), and motor imitation (four items). The items selected for inclusion are those that were found to discriminate between 2-year-old children with autism and developmentally matched comparison samples (Stone et al. 2000). Although the STAT was designed for use with children between the ages of 24 months and 36 months, preliminary evidence for its utility with children as young as 14 months has been obtained (Stone et al. 2008), and ongoing research is being conducted to evaluate its use with 3-year-old children.

The STAT was designed for use by a broad range of community service providers working with young children, such as early intervention providers, birth-to-three personnel, preschool teachers, psychologists, speech-language pathologists, and health-care professionals. It can be used in clinical, educational, and home settings. It takes about 20 min to administer and was designed to be scored live. Training on the STAT is available through participation in 1-day workshops (see <http://uwreadilab.com/our-workshops/>) or completion of a web-based tutorial (see <http://vkc.mc.vanderbilt.edu/vkc/triad/training/stat/>).

STAT training workshops have been conducted in countries around the world, and it has been translated into Spanish, Mandarin, and Polish.

The STAT User's Manual contains information about the purpose and use of the STAT, describes its development and psychometric properties, and provides general information, guidelines, and tips regarding the administration and scoring of each item. The STAT Materials Kit contains all of the play materials needed for the screening, such as a ball, toy car and truck, puppet, baby doll, bubbles, balloons, and many others. The STAT Test Protocol contains detailed instructions regarding the number of trials allowed for each item and the specific wording of verbal directions and prompts, along with scoring criteria and examples for each item.

Administration of the STAT involves setting up situations to elicit key social and communication behaviors. The play items on the STAT assess the child's participation in a turn-taking game and his/her functional play with a doll. The requesting items involve presenting desired objects in closed containers and observing whether and how the child asks for help or more, either verbally or nonverbally. The directing attention items involve creating unexpected events and observing whether and how the child shares interest or enjoyment in the event with the examiner. The imitation items assess the extent to which the child attempts or succeeds in imitating simple actions demonstrated by the examiner. Multiple trials can be given for most items, and the child's item score reflects his/her best performance on the item. Specific scoring criteria are used to determine whether the child's performance on each item is a pass, fail, or refuse. The average number of fails for each of the four domains is summed and compared to a cutoff score to identify the child's risk for autism.

Administration of the STAT was designed to be developmentally sensitive and to optimize the child's interest and attention. Language demands are minimal. Although instructions, prompts, and materials are standardized, the sequence in which items are administered can be adapted to the needs of the child. Likewise, items can be administered on the floor or at a table as needed to engage the child and elicit his/her best performance.

Historical Background

Development of the STAT began in the mid-1990s, after a growing empirical literature at the time indicated that (a) autism could be diagnosed accurately at age 2 and (b) behaviors in the social and communication domains were the most prominent characteristics at that age. It was developed at Vanderbilt University by Wendy Stone, PhD, a professor of pediatrics, and Opal Ousley, PhD, who was a psychology graduate student at the time. The purpose of the STAT was to facilitate the early identification of autism by directing children in need of autism-specialized services to assessment centers with the necessary experience and expertise to diagnose autism at young ages. The STAT was designed as a second-stage screener for use in referral (vs. primary care) settings. That is, the purpose of the STAT was to identify children at specific risk for autism from more heterogeneous groups of children for whom there were developmental concerns.

The first STAT Training Workshop was conducted in 1999, and the first published study describing the STAT appeared in 2000 (Stone et al. 2000). Subsequent publications have provided additional information about its psychometric properties for 2-year-olds (Stone et al. 2004) and for children under 24 months (Stone et al. 2008). The web-based STAT Training Tutorial (Kobak et al. 2011) became available in 2009.

The development and refinement of the STAT is ongoing. Current projects are examining its utility for screening in 3-year-olds, the use of a continuous scoring system for each item, and the inclusion of ratings for social engagement and atypical behaviors.

Psychometric Data

Use of the STAT with 2-Year-Olds

The psychometric properties of the STAT were reported in 2004 (Stone et al. 2004). The results, described below, demonstrate strong psychometrics with respect to screening properties, test-retest reliability, interobserver agreement, and concurrent validity with the ADOS.

Screening Properties. The screening properties of the STAT (i.e., sensitivity, specificity, positive predictive value [PPV], and negative predictive value [NPV]) were evaluated on a sample of 52 children, 26 with autism and 26 with developmental delay and/or language impairment (DD/LI). Participants were referred for diagnostic evaluations from a variety of clinical settings between 1997 and 2000. Eligibility criteria were the following: chronological age between 24 and 36 months (i.e., between 2 years, 0 months, 0 days and 2 years, 11 months, 29 days), absence of severe sensory or motor impairments, and absence of identified genetic disorders. All data were collected during the course of the child's diagnostic evaluation, which was conducted by a team of clinicians that included a licensed psychologist and a licensed speech-language pathologist. Autism diagnoses were made by the team psychologist, based on criteria provided in DSM-IV (APA 1994). The STAT was administered by trained examiners who were independent from the diagnostic team and were blind to the results of the diagnostic evaluation. Likewise, the team clinicians were blind to the results of the STAT screening.

Development and validation samples were created to include equal numbers of children with autism and children with DD/LI. There were no diagnostic group differences for chronological age, mental age, or maternal level of education in the development or validation sample. Signal detection using the development sample identified a score of 2 or higher as the optimal cutoff for autism risk. Applying this cutoff score to the validation sample resulted in a sensitivity of 0.92, specificity of 0.85, PPV of 0.86, and NPV of 0.92, providing strong support for its screening properties using this scoring algorithm.

Concurrent validity was assessed by comparing STAT risk category (at risk vs. not at risk) with diagnostic classification (autism vs. nonspectrum) on the Autism Diagnostic Observation Schedule (ADOS; Lord et al. 2000) in a sample of 82 children. The STAT and ADOS were administered by different examiners who were blind to the results of the other's evaluation. Cohen's kappa for agreement between STAT risk category and

ADOS classification was 0.95. Only two children were identified incorrectly by the STAT; both were identified as high risk by the STAT but did not meet ADOS criteria for autism (i.e., false positives).

Interobserver agreement for STAT risk category was evaluated by having two examiners score the STAT independently for 29 children (14 with autism, 2 with PDD-NOS, and 13 with DD/LI). Interobserver agreement was 1.00 using Cohen's kappa.

Test-retest reliability for STAT risk category was examined by having 21 children (nine with autism, six with PDD-NOS, and six with DD/LI) participate in two STAT screenings approximately 2 weeks apart (mean delay = 20 days, range = 4–44 days). Different examiners administered the STAT at each time point to reduce any potential familiarity bias. Test-retest reliability was 0.90 using Cohen's kappa.

Use of the STAT with Children Under 2 Years Old

A preliminary investigation of the utility of the STAT for children under 24 months of age was published in 2008 (Stone et al. 2008). This study included 71 children (44 male, 27 female) who received the STAT between 12 and 23 months of age and a follow-up diagnostic evaluation after 24 months. The average length of time between the initial and follow-up visits was 15 months. All children were at elevated risk for autism by virtue of having an older sibling with an autism spectrum diagnosis ($n = 59$) or being referred for evaluation for concerns about autism ($n = 12$).

The STAT was administered and scored in the same manner as for the 2-year-old samples (Stone et al. 2004), without any procedural or scoring changes. Signal detection analysis with the entire sample revealed that the STAT cutoff score of 2 demonstrated high sensitivity (1.0) but low specificity (0.40) for this age group. The optimal cutoff score for this young sample was 2.75; this cutoff yielded a sensitivity of 0.95, specificity of 0.73, PPV of 0.56, and NPV of 0.97. However, it was also observed that false positives were highest (38%) for the 12–13-month-old age group. When the sample was limited to children

14 months and older, STAT screening properties for a 2.75 cutoff improved to a sensitivity of 0.93, specificity of 0.83, PPV of 0.68, and NPV of 0.97. These results provide preliminary support for the use of the STAT in children between 14 months and 23 months of age, using a cutoff score of 2.75. Replication with an independent sample is currently under way.

Clinical and Community Use

The STAT can be used by a variety of service providers in a diverse array of settings to facilitate early identification and early intervention for children with autism. A “screen-positive” result on the STAT can indicate the need for referral to professionals who have specialized training and experience working with young children with autism. For example, in state birth-to-three systems, service providers or coordinators can screen children with the STAT to identify those at risk for autism, so that timely referrals can be made to diagnosticians and interventionists with specialized experience and training. In community-based intervention settings, such as speech-language clinics, clinicians can use the STAT to screen children on their caseload to determine their need for further diagnostic evaluation for autism. In diagnostic assessment settings, children on the waiting list can be screened with the STAT so that they can be routed to the clinicians with the most experience and training in assessment and early diagnosis of autism.

Several community-based research projects have examined the utility of the STAT as a component of a larger assessment battery focused on early autism detection of autism. For example, the STAT is the centerpiece of a program designed to train pediatricians in community practice settings how to conduct autism assessments (i.e., the STAT-MD program). In this program, pediatricians learn how to administer and score the STAT, as well as how to conduct developmentally sensitive parent interviews and use incidental observations to form diagnostic impressions within a DSM-based framework (Swanson et al. 2014; Warren et al. 2009). More recently, the

STAT has been integrated into Project ECHO, which provides training to primary care providers through a technology-based mentorship model. Participants in ECHO Autism STAT receive training in the screening and diagnosis of children at highest risk for autism (Mazurek et al. 2019).

The STAT has also been used in conjunction with Level 1 (i.e., population-based) screening tools to identify children who may benefit from a more in-depth autism evaluation. One study of this two-tiered screening model in pediatric practices found evidence supporting the combined use of the M-CHAT and the STAT for reducing false positive results (Khowaja et al. 2018). A 2-tiered screening model was also used in a statewide early intervention system in South Carolina, where children who screened positive on general developmental screens received the STAT (Rotholz et al. 2017). Results revealed that this approach led to increased detection and earlier access to behavioral intervention for young children with autism. The potential use of a two-threshold STAT scoring system, which identifies children at highest and lowest autism risk, was demonstrated within an early intervention system (Roberts et al. 2019). In addition, the STAT was found to be suitable for use by community providers as a second-stage case confirmation tool for epidemiological risk factor research in prospective cohorts (Newschaffer et al. 2017).

In addition to providing a cutoff score to identify autism risk, the interactive nature of the STAT affords the opportunity for other clinical uses. The STAT provides a standard setting for obtaining a rich sample of behaviors that represent core social and communicative deficits in autism. During a 20-min STAT screening, clinicians can obtain important information about the child’s strengths and needs in the areas of object play, turn-taking, communication, and imitation. This information can then be used to identify specific intervention goals and to design targeted teaching activities. For example, special educators have used the STAT to prepare preliminary educational plans for children who will be entering their school system at age 3. Similarly, children’s performance on the STAT can be used to formulate and initiate

individualized teaching activities during the often-long waits between the suspicion of autism and the child's formal diagnostic evaluation. A workbook for this purpose has recently been developed.

Research projects have also capitalized on the standardized yet brief behavioral sample afforded by the STAT. For example, the STAT Total and Directing Attention scores have been found to differentiate between groups of toddlers at high and low risk for autism (Stone et al. 2007). The Imitation domain score was used in a study examining predictors of language development in toddlers at elevated familial risk for autism (Edmunds et al. 2017). The STAT has also been used successfully as a context for coding social-communicative behaviors such as initiating joint attention, positive affect sharing, and repetitive behavior (McDuffie et al. 2005; Yoder et al. 2009). In addition, the STAT has been used to screen children under 24 months for eligibility for participation in research projects (Carter et al. 2011).

[Social scripts](#)

Definition

Scripts are written, audio, and/or pictorial examples of phrases or sentences that children with disabilities can use in specific social or academic situations. The individual is explicitly taught the script through modeling, prompting, and reinforcement and then prompted to use the script in the specific situation for which it was developed. Following successful use of the script, a script-fading procedure should be implemented to fade the use of the script over time. Scripts can be used to increase social initiations (e.g., “what do you want to play?”), provide suggestions to improve conversational skills (e.g., “my favorite movie is”), or request assistance (e.g., “help please”).

The use of scripts has improved the communication and social interaction skills that are prevalent in individuals with autism spectrum disorder (ASD; Ganz et al. 2008). Individuals with ASD benefit from the use of scripts in both academic and nonacademic settings, including home, workplace, and community. Scripts have been shown to be effective with children who have minimal language and reading skills (Krantz and McClannahan 1998), for nonreaders using an audio taped script and script-fading procedure (Stevenson et al. 2000), as well as for those with extensive verbal skills, but poor social skills (Krantz and McClannahan 1993). Social scripts can reduce the stress associated with social interactions and assist the child by helping them understand the perspective of others and by providing them with age-appropriate social language. Including informal language, slang, or child-specific terms in the social script may help the conversational exchange appear more natural (Kamps et al. 2002). Although script-fading procedures have demonstrated an increase in the number of unscripted social interactions emitted by research participants (Krantz and McClannahan 1993, 1998; Stevenson et al. 2000; Wichnick et al. 2010), few studies have demonstrated stimulus generalization until recently. Brown et al. (2008) demonstrated a systematic increase in unscripted interactions, and these interactions generalized to untrained stimuli. Further, Wichnick-Gillis et al. (2016) demonstrated the effectiveness of the script-fading procedure in increasing interactions of children with autism towards peers and were able to incorporate cues in the natural environment that served as discriminative stimuli for social interactions. This shift to embedding cues within the natural environment will likely lead to greater generalization when using scripts to promote language and social interaction skills for individuals with autism.

Seasonality of autism

Definition

Seasonal variations in rates of autism might reflect the operation of environmental factors in pathogenesis; however, empirical support for seasonality is decidedly mixed. Landau et al. (1999) carefully investigated eight studies that had served as support for the seasonality hypothesis as an etiological factor in the development of autism. More specifically, the authors of these studies have reported a higher autistic birth rate in spring (March) and in Autumn (August) with a significant deficit of autistic births in the fall and winter months. A detailed examination of each of the eight investigations revealed a number of methodological problems that served to call into question, the validity of these claims of support for the seasonality theory of the genesis of autism.

Major methodological and bio-statistical flaws are noted as were how they were controlled in the Landau et al. investigation:

- Each of the eight studies utilized the general “live population” from which the autistic sample was drawn, thereby potentially biasing the reported results (Fombonne 1989).
- *The author and collaborators utilized ID non-Autistic subjects as a control.*

The comparison population in two of the eight studies defined the general population to contain live births only (i.e., Barak et al. 1995). As noted by Dalen (1975) and Hare (1975), this sampling bias does not take into account infant mortality, which can potentially produce later skewing of the monthly distribution of births

- *The ID non-Autistic control group applies to this methodological flaw as well.*

Relative to the statistical procedures that were employed, the sample sizes in many of the studies were not sufficiently large (e.g., the study by Gillberg 1990).

- *The sample sizes for autism and comparison groups varied markedly.*

As correctly noted by Bartik (1981), the repeated application of the chi-square (d) test without controlling for Type 1 error will lead eventually to confusing statistically significant results with those that have occurred on the basis of chance alone.

- *The earlier study utilized chi-square (d) appropriately as well as introducing a novel statistic that appears very well designed to test the seasonality hypothesis in autism.*

In order for a seasonal finding to be plausible in a biological sense, birth rates should not be restricted to 1 month only; this is because adjacent months would presumably also be affected.

- *This methodological concern was addressed in a twofold manner: first, the seasonality hypothesis was tested by examining the numbers of Autistic births both at the beginning and middle of March and August; and secondly, by determining the highest birth month for each of the study groups.*

In addition, the number of study groups was strongly influenced by the results of research

investigations showing a robust correlation between cognitive impairments and neurobiological deficits among children (Gillberg 1988; Rutter 1983). The implication of these two studies is that children who are more cognitively impaired are more likely to experience a seasonality-of-birth effect. Therefore, in order to test the seasonality hypothesis in autism, it required four study groups: (1) Autistic-Mute (AM); (2) Autistic-Verbal (AV); (3) Intellectual Disability-Mute (IDM); and (4) Intellectual Disability-Verbal (IDV). The prediction was that, in accord with the seasonality hypothesis in autism, the groups would order themselves, for both March and August births as: AM, AV, IDM, and IDV. Put in clinical research terms, the investigators were testing for an ordinal trend with a dichotomous outcome. The statistic that seemed most appropriate was Jonckheere's 1970 test for analyzing ordinal trends with a dichotomous outcome. The authors utilized a computer program designed by Cicchetti et al. (1992). The statistic was utilized in this investigation to study the correlation between the severity of neuropsychological symptomatology to differences in verbal and performance IQ. It was used more recently to examine the relationship between age and the effects of mercury exposure among dentists and controls (Duplinsky and Cicchetti 2012).

Results not only indicated no support for the seasonality hypothesis, some of the findings, somewhat paradoxically, showed results that trended in a direction that was opposite the hypothesis.

More Recent Test of the Seasonality Hypothesis in Autism

Published in 2012, Mazumdar et al. performed another test of the seasonality hypothesis in autism. The main rationale for the study was the argument that date of birth (DOB) is biased, because factors associated with the development of autism have occurred prenatally. As a consequence, the authors therefore argued for utilizing

time of conception, rather than DOB, for testing the seasonality hypothesis. There are four reasons for arguing against this position: The first is a problem of definition. DOB is arguably a very accurate concept. Conception, however, as the authors define it, is not nearly as accurate or valid a measurement. Thus, Mazumdar et al. (2012, p. 4) define it as “The Birth Master File (BMF) also contains the date of the mother’s last menses to which we added a fortnight to obtain an approximate date of conception.”

The second problem is that the authors do not explain why DOB should, of necessity, be considered a biasing factor when whatever occurred prenatally would, at DOB or shortly thereafter, manifest as autism, etiologically. The third problem is that Mazumdar and co-authors also reported that seasonality of autism has been “disappearing” over recent years, in California, where the study took place. The scientific question here is why would this occur if the etiology of the problem was truly related to the genesis of seasonality in autism? It should be stressed that the title of the Mazumdar et al. publication is: *The Disappearing Seasonality of autism Conceptions in California*. In conclusion, the interpretation of the findings of this study appear to be flawed. It should finally be noted that the authors of a very well-designed study in Germany have argued convincingly that research focusing on conception should be prospective rather than retrospective (Gnoth et al. 2003). This is once again, because of the inaccuracy of estimates of precisely when conception has taken place.

Definition

This entry addresses topics regarding students with autism spectrum disorder (ASD) without intellectual disabilities (ID) in secondary and postsecondary education. This is a group of individuals on the autism spectrum that is often referred to as having a *higher functioning autism* (Zeliadt 2016) or has been diagnosed with Asperger syndrome according to The International Classification of Diseases and Related Health Problems (ICD-10) (World Health Organization 1992). One of the hallmarks of ASD is to have challenges when it comes to social communication, thus making students with ASD at risk of being socially excluded in school settings. In this entry, we address issues pertaining to students with ASD without ID's school – and student life, especially issues regarding social experiences and mental well-being.

Historical Background

Over the past several decades, there has been an increasing number of those diagnosed with ASD with average or above average intellectual ability, many of whom are likely to attend mainstream

high school and subsequently pursue a postsecondary education (Jackson et al. 2018b). Furthermore, in line with the global ideology of inclusion on social and educational policy, students with ASD are more likely to attend mainstream schools and enroll into colleges than before (Nilsen 2017; Øien and Nordahl-Hansen 2018). Students with ASD without ID may receive special education support depending on their needs. In a more long-term perspective, many adults with ASD without ID struggle when it comes to issues such as working life, independent living, and establishing intimate relationships (Koegel et al. 2012).

Current Knowledge

Studies show that individuals with ASD without ID experience an increased feeling of loneliness and isolation during adolescence (Lasgaard et al. 2010). Demands on social skills accentuate during teenage years, adding more pressure on students with ASD who already have challenges with social communication (White and Robinson-Nay 2009; Øien et al. 2019). Similarly, many adults with ASD experience that the feeling of loneliness grows stronger as they become older (Müller et al. 2008). Approximately a third of individuals with ASD without ID suffer from depression and anxiety (Koegel et al. 2012). Locke et al. (2010) conducted a study with the objective to research socioemotional aspects of students with high-functioning ASD in mainstream high schools. Even though the students with ASD were in an inclusive school setting, they experienced a higher degree of loneliness than their typically developed (TD) peers. Also, findings from a systematic review of literature unfolding friendship among children and youth with high-functioning autism (Petrina et al. 2014) showed that friendship can be a difficult aspect of school. The review showed that these children and youths had less friends and had more fragile friendships than their TD peers. The students with ASD also had fewer interactions with peers outside the school setting. Correspondingly, over three quarters of 56 college students with ASD reported having regular

struggles of feeling of loneliness and isolation (Jackson et al. 2018b). Students with ASD are also at risk of school refusal behavior. A Norwegian study showed that school refusal behavior was significantly higher in students with ASD without ID, as compared to TD students (Munkhaugen et al. 2017). In addition, the study showed that students with ASD without ID were more at risk of school refusal behavior than students with ASD and ID. Likewise, college students with ASD are at risk of dropping out before graduating (Jackson et al. 2018b) thus finishing their degree at a lower rate than their TD peers (Jackson et al. 2018b). Bullying is also a topic of great concern when it comes to students with ASD. Research show that students with ASD both with and without ID are more at risk of being bullied than their neurotypical peers and subsequently suffer from depression and anxiety (Williams et al. 2017; Weinstock 2018). Although bullying often decreases when students become of age, autistic college students may still experience being bullied in their college years (DeNigris et al. 2018). In fact, being bullied may increase suicidal behavior in individuals with ASD (Weinstock 2018). In a recent study of 56 college students with ASD, as many as three quarters of the participants reported lifetime suicidal behaviors (Jackson et al. 2018b). Further, some studies show that individuals with ASD without ID are particularly at risk of suicide (Richa et al. 2014).

Findings from a metasynthesis of 31 qualitative studies by Williams et al. (2017) proposed that inclusive mainstream settings may heighten many pupils with ASD's sense of being "different" from TD peers in a negative way, thus increasing their risk for developing low self-esteem and mental health problems. Most of the participants in the metasynthesis were in their teenage years. Further, in a study by Elias and White (2018) of the needs of college students with ASD from their parents' perspective, the results suggested that college students struggle with social tasks and independent living. The results further suggest that these difficulties are impairing when it comes to finishing their postsecondary degree (Elias and White 2018). Additionally, school transition is a topic known to be challenging for

students with ASD (Nuske et al. 2018). However, a recent study showed that school transitions may be perceived as a new and positive start for some (Skafle et al. 2019). The students in this study, all diagnosed with Asperger syndrome, expressed that they felt included by their high school peers and teachers and appreciated leaving their former classmates in order to start "fresh" and entering a new role with new people. These students also expressed that their social skills improved by being social with their peers in school. Previous research also shows that TD students can be of good support and become role models for ASD students (Koegel et al. 2012). In order to support ASD students, there are different types of interventions especially targeted at educating social skills, with the objective of subsequently improving these students' social life in schools and colleges. Interventions may be short term and long term and focus on one specific social skill or several at the time (Ke et al. 2018). Moreover, different people surrounding the ASD student, such as parents, friends, clinicians, teachers, or special education teachers, can be responsible for the interventions (Mundy and Mastergeorge 2012).

Future Directions

In order to support the needs of students with ASD without ID in high schools and colleges, more research about the unique needs of students with ASD must to be undertaken, as there are a limited number of previous studies. It is likely that the rate of individuals with autism who graduate will rise with better support and thus finish their degree at the same level as their TD peers. In the USA, only 40% of students with ASD finished their post-secondary degree compared to 60% of TD students (Kuder and Accardo 2018). Moreover, in order to understand the needs of high school students and college students with ASD, it is necessary to investigate what works from their own perspective. So, in addition to investigating challenges, one needs to look further at positive outcomes and also listens to the ASD community itself.

Secondary Handicapping Conditions

Jacqueline Kelleher

Education, Sacred Heart University Isabelle
Farrington School of Education, Southern
Connecticut State University, Fairfield, CT, USA

Synonyms

Comorbidity

Definition

Secondary handicapping conditions involve additional characteristics of other disabilities or disorders that may affect an individual to a lesser degree than the primary disability or disabling conditions, leaving marked impairment on the lives of individuals. Secondary conditions have been defined as “those physical, medical, cognitive, emotional, or psychosocial consequences to which persons with disabilities are more susceptible by virtue of an underlying condition, including adverse outcomes in health, wellness, participation, and quality of life” (Hough 1999, p. 186). Individuals on the autism spectrum are likely to experience additional deficit areas or secondary handicapping conditions as a result of comorbidity of one or more of the following conditions, disabilities, or disorders related to vision, depression, tuberous sclerosis, general anxiety disorder, Tourette’s syndrome, obsessive compulsive disorder, bipolar disorder, attention deficit hyperactivity disorder, Fragile X syndrome, intellectual/cognitive disabilities, seizure disorder, epilepsy, sensory integration, oppositional defiance disorder, depression, neuroinflammation disorders, immune disorders, nonverbal learning disorders, motor clumsiness, and gastrointestinal distress/bowel disease.

Definition

Secretin, a digestive polypeptide hormone secreted in the upper part of the small intestine, stimulates the pancreas to secrete water and

bicarbonate, thus neutralizing hydrochloric acid that passes from the stomach into the duodenum. It is most commonly used in a synthetic form to evaluate pancreatic function.

In the late 1990s, extensive media coverage was given to a single case in which a 3-year-old child with autism who received intravenous secretion as part of a pancreatic assessment for gastrointestinal issues showed improvements in speech and behavior soon afterward. A subsequent case study series of three young children with autism who also received secretin as part of gastrointestinal evaluations reported improvements in language and social abilities in addition to the amelioration of gastrointestinal issues (Horvath et al. 1998). Based largely on the single case anecdotal report, the three-case series, and compelling anecdotal evidence, media reports publicized secretin as a treatment for autism. However, the case series had significant methodological limitations, and no empirical evidence supported the treatment. Concern over the widespread off-label use of secretin as a treatment for autism was expressed in the medical and research community (Volkmar 1999).

In response to the media frenzy and escalating off-label use of the hormone, a series of randomized, double-blind studies investigated the effects of secretin on children with autism. Sandler et al. (1999) randomly assigned 56 children diagnosed with either autism or PDD-NOS to receive either secretin or placebo saline infusions. They were assessed at baseline, immediately after infusion, and for 4 weeks postinfusion. The main findings were twofold: first, scores on the 16 outcome measures or assessment domains were not significantly improved with secretin treatment versus with placebo. Second, both secretin and placebo groups had significant decreases from baseline in autism symptoms over the 4-week period. Similarly, Coniglio et al. (2001) assessed 57 randomly assigned participants at baseline, 3 and 6 weeks postsecretin or placebo administration by parent report and clinical behavior testing. While a marginally significant improvement was seen at 3 weeks posttreatment for secretin, at 6 weeks neither group showed significant change in assessment from baseline.

In 2000, Chez et al. undertook a two-part study to further investigate the anecdotal claims of secretin treatment. First, 56 children were administered one dose of secretin and evaluated at baseline and several weeks postinfusion. Overall, the group had minimal improvement in behavior and language abilities, but not significant gains at a clinical level. Next, 17 of the most responsive subjects and an additional eight new subjects entered a double-blind trial of secretin and placebo with a 4-week crossover. They were evaluated by parent report at baseline, at 4 weeks, and at 8 weeks. Results of the second study did not demonstrate any significant behavioral differences between patients treated with placebo and secretin when the administration was double-blind and placebo controlled. Likewise, no significant improvement was seen in autism behaviors as assessed by parent and teacher report in a study of eight children who received secretin or placebo in a randomized double-blind study, also with a 4-week crossover (Carey et al. 2002). In fact, the majority of changes seen were behavioral improvement after placebo and deterioration after secretin. Taken together, these studies suggest a lack of evidence for secretin as a viable treatment option.

Section 504 of the Rehabilitation Act of 1973

Oren Shtayermman

New York Institute of Technology Mental Health Counseling, Old Westbury, NY, USA

Definition

In 1973, President Carter engaged into law the Rehabilitation Act (P.L. 93-112; U.S. Congress 1973). This Act provided for a number of provisions subsequent in newfangled shields and rights for persons with disabilities. Section 504 of the Rehabilitation Act stated that “no otherwise qualified handicapped individual in the United States shall, solely by reason of his handicap, be excluded from participation in, be denied the benefit of, or be subjected to discrimination under the program or activity receiving Federal financial assistance.” According to Section 504, individual with disability means any person who:

1. Has a physical or mental impairment which substantially limits one or more major life activities
2. Has a record of such impairment
3. Is regarded as having such impairment

Students eligible for services under these provisions include some of the following groups:

1. Students with disabilities whose learning is impacted and those with attention deficit

disorder, attention deficit/hyperactivity disorder, immune disorders, allergies, learning disabilities, and hearing impairments

2. Those who have been misdiagnosed or labeled with a disability
3. Students with AIDS and other contagious diseases such as hepatitis B and tuberculosis
4. Students who experience temporary disabling circumstances such as those due to injuries

Section 504 essentially mandates that school districts must provide accommodations that include health related services that enables students to attend school. Schools must create a Section 504 accommodation plan to address how the school will insure that the student is not discriminated against upon the basis of their disability. Unlike IEPs under IDEA, Section 504 Accommodation Plans are unfunded.

Secure Employment

S. Michael Chapman

TEACCH Autism Program, University of North Carolina Chapel Hill, Chapel Hill, NC, USA

Definition

Secure employment is an employment scheme designed for individuals that are not presently able to perform in competitive employment or supported employment settings. Secure employment is a facility-based program that utilizes a structured environment where individuals are guaranteed employment without the fear of losing employment due to intrusive behaviors. While in secure employment, trained staff work with the individuals to develop greater vocational independence and appropriate behavioral skills necessary for potential integration or reintegration into competitive or supported employment.

Sedative Hypnotic Drugs

Jeffrey Glennon

Department of Cognitive Neuroscience, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

Synonyms

Barbiturates; Benzodiazepines

Indications

Anxiety, Sedation, Sleep disturbances

Mechanisms of Action

Both barbiturates and benzodiazepines exert their primary mechanism of action by interacting with the GABA_A receptor. The GABA_A receptor is a heteromeric receptor containing five subunits, most commonly two alpha subunits, two beta subunits, and one gamma subunit. GABA_A receptor alpha, beta, and gamma subunits can be of several subtypes (alpha1-6, beta1-3, and gamma1-3). Different subunit compositions can lead to different types of GABA_A receptor that have different expression and function throughout the CNS.

Barbiturates

Barbiturates act by a mixture of several mechanisms dependent on the dose employed. The primary mechanism of action is by potentiating the action of the inhibitory neurotransmitter GABA by binding to GABA_A receptor alpha subunits (which are distinct from both the GABA and benzodiazepine binding sites). This leads to an increase in the duration of chloride ion channel opening at the GABA_A receptor which potentiates the action of GABA. Furthermore, barbiturates also block the action of the excitatory neurotransmitter glutamate by blocking glutamatergic

AMPA receptors. At higher doses, barbiturates also block the Ca²⁺-dependent release of neurotransmitters. Taken together, barbiturates exert potent CNS depressant effects via these mechanisms.

Barbiturates have also been shown to bind to other ligand-gated ion channel targets including the neuronal nicotinic acetylcholine receptor, the serotonin 5-HT₃ receptor, and the glycine receptor family, suggesting that their therapeutic and side effects may also depend on these other potential mechanisms of action.

Benzodiazepines

Benzodiazepines act primarily by potentiating the action of the inhibitory neurotransmitter GABA by acting on benzodiazepine binding sites which form part of GABA_A receptor complexes modulating GABAergic receptor function in the CNS. This serves to promote the binding of GABA to its binding sites on the GABA_A receptor which increases the conductance of chloride ions across the coupled ion channel leading to membrane hyperpolarization and inhibition. These benzodiazepine-binding sites are situated at the junction between alpha and gamma subunits on the GABA_A receptor. Interestingly, benzodiazepine binding can only occur at those GABA_A receptors expressing alpha subunits with a histidine amino acid residue (alpha 1, 2, 3, 5). For this reason, benzodiazepines have no effect on GABA_A receptors containing alpha 4 or alpha 6 subunits which have an arginine amino acid residue instead of a histidine one. It is notable that different benzodiazepines have differential effects of different GABA_A populations dependent on the subunit composition. For example, those with higher affinity for GABA_A receptor populations expressing alpha 2 and/or alpha 3 tend to show more marked anti-anxiety effects, while those with an affinity to alpha 1 containing GABA_A receptors demonstrate increased hypnotic activity.

Outside of the CNS, benzodiazepines also bind to peripheral benzodiazepine receptors that are not structurally or functionally coupled to the

GABA_A receptor but are expressed predominantly in the peripheral nervous system and glia, suggesting immunomodulatory actions. It has also been reported that benzodiazepines also act as weak antagonists at adenosine receptors which may play a role in their anxiolytic, muscle relaxant, and anticonvulsant effects.

Key sites of action for both barbiturates and benzodiazepines include binding sites in the spinal cord (exerting muscle relaxant effects), brainstem (accounting for anticonvulsant properties), cerebellum (inducing ataxia), and cortic limbic brain regions (regulating emotional and behavioral effects).

Specific Compounds and Properties

Barbiturates

Thiopentone and methohexital (very short duration of action) are employed as anaesthetic-induction agents. Secobarbital (short duration of action), butobarbital (medium duration of action), phenobarbital (long duration of action). Barbiturates are associated with drowsiness, tolerance, increased risk of overdose, and possible physical and psychological dependence with severe withdrawal symptoms.

Benzodiazepines

Chlordiazepoxide (prototype of benzodiazepine class; introduced in the 1930s), diazepam (extensively used; rapid onset of action; *N*-desmethyldiazepam (nordiazepam) is the major active metabolite; long half-life (60 h)), lorazepam (rapid onset of action; half-life of 12 h), temazepam (half-life of 10–15 h), flunitrazepam (potent; short duration of action; half-life of 10–20 h), alprazolam (half-life of 9–16 h), oxazepam (half-life of 12 h), nitrazepam (long duration of action; half-life of 25–35 h), flurazepam (long duration of action (via metabolite)), lormetazepam (medium duration of action; half-life of 10–12 h), loprazolam (short half-life; slow absorption), triazolam (short duration of action; half-life of 3–4 h; sedation at higher doses), zopiclone (binds near but not at the benzodiazepine receptor; half-life of 5–8 h dependent

on age of subject; lower degree of side effects compared to other benzodiazepines while retaining sedative hypnotic actions), eszopiclone (*s*-enantiomer of zopiclone; approved in the USA for long-term insomnia treatment), zolpidem (rapid absorption; short half-life (0.7–3.5 h), low side-effect profile), zaleplon (very short half-life of 1 h; low side-effect profile; reduces sleep onset).

Clinical Use (Including Side Effects)

The term “sedative” originally pertained to therapeutics that allayed anxiety although its more current usage is more often associated with drowsiness or torpor. This originally included barbiturates as a drug class versus what was originally perceived as nonsedative properties of benzodiazepines. This distinction is artificial with both drug classes having similar clinical and pharmacological profiles with marked anxiolytic properties. Hypnotics pertain to the sleep-induced properties of these therapeutics, and as such, sedative hypnotics as a drug class best pertain to benzodiazepines, although other classes such as barbiturates, gamma-aminobutyric-acid (GABA) analogues, and anti-epileptic drugs have sedative hypnotic effects. However, the more severe side-effect profiles (including increased risk of death with overdose) of barbiturates have led to their replacement in routine clinical use by benzodiazepines.

The clinical utility of barbiturates has been surpassed by the adoption of benzodiazepines as safer sedative hypnotics. Barbiturates have been employed primarily in the past as anxiolytic and sedative agents with some such as phenobarbital still retaining clinical usage as anticonvulsants. Due to the risk of death with overdose, their clinical use must be carefully monitored particularly with regard to their CNS depressant effects which can mediate side effects as varied as respiratory depression, postural hypotension, confusion, fatigue, and impaired concentration/decision-making.

Benzodiazepines are most commonly employed in the symptomatic control of anxiety and stress-related conditions, although regulatory approval is usually for panic disorder and

generalized anxiety. Irrespective of origin, these anxiety symptoms are the primary clinical indication of these therapeutics. While anxiety disorders can be both short and long lasting, benzodiazepines are usually used for the symptomatic management regardless of symptom duration. Given the long half-life of some benzodiazepines such as diazepam, treatment can be taken once daily but patients often prefer the reassurance of twice-daily administration claiming that they perceive anti-anxiety effects directly after each dose. For episodic anxiety, short duration of action benzodiazepines such as lorazepam taken before exposure to the anxiety generating situation exert potent effects while also exerting anti-anxiety effects when taken during a panic attack. This preventive effect against panic attacks has also been claimed for other benzodiazepine such as alprazolam. However, discontinuation of benzodiazepine treatment often results in relapse or even rebound panic episodes. Benzodiazepines with a short duration of action are also employed adjunctively to relaxation therapy. Overdosage with benzodiazepines is common, but associated deaths are fortunately rare. However, extreme caution must be taken in terms of dose regulation in children, especially in those with preexisting respiratory complaints. Benzodiazepine effects are potentiated in the presence of other depressant drugs such that the consumption of alcohol while being treated with benzodiazepines is not advised. In situations where benzodiazepines and alcohol are concurrent, the patient often falls into a deep sleep but can be aroused following administration of the benzodiazepine antagonist flumazenil or similar drugs.

Hypnotic effects of both barbiturates and benzodiazepines are most commonly employed against sleep disturbances, notably insomnia. The cause of the sleep disturbance should be investigated first and if possible resolved through other means as the utility of long-term benzodiazepines may result in paradoxical sleep disturbances. Often, anxiety/stress can precipitate sleep disturbances, and resolution of these problems will reduce the need for long-term benzodiazepine use. If used for their hypnotic effect, those benzodiazepines with a shorter half-life are

preferred to avoid excessive sleeping through the 24-h cycle. Of note, 5–10 mg diazepam once at night or temazepam (which has a half-life of 10–15 h) can induce sleep onset without many residual side effects the next day, while nitrazepam with a longer half-life (25–35 h) is employed to both manage anxiety during the day and induce sleep at night. While the hypnotic use of most benzodiazepines are often utilized prophylactically prior to the patient going to bed, the newer drugs such as zolpidem and zaleplon can be taken on an “as needed” basis if natural sleep onset fails after retiring to bed. This reduces the risk of dependence on these drugs and given their short duration of action reduces the side-effect profile associated with their utility.

Tolerance to moderate doses of barbiturates or benzodiazepines can occur, necessitating an increase in dosage to achieve anti-anxiety effects. However, as the stress/anxiety resolves, stepwise decreases in dosage should also be considered. Long-term clinical studies of barbiturate and benzodiazepine usage in autistic populations are lacking, but withdrawal of medication often results in relapse, suggesting that maintenance ensures continuation of the anti-anxiety effects or at least an avoidance of rebound effects. Dependence can occur at higher doses with drug withdrawal precipitating relapse 2–4 days or 5–10 days post-discontinuation in the case of short- and long-acting benzodiazepines, respectively. Withdrawal symptoms often include anxiety, apprehension, dizziness, insomnia, confusional psychoses, and anorexia. Physical dependency can precipitate withdrawal symptoms such as muscle weakness, postural hypotension, convulsions, tremor, and nausea and vomiting. As such, it is best to reduce the dose gradually in order to minimize the risk of withdrawal symptoms which often ensue following abrupt termination of benzodiazepine use.

Oversedation of subjects results in the most commonly reported side effects of barbiturates and benzodiazepines: drowsiness, tiredness and torpor which are both dose- and time dependent. Drowsiness is typically observed within the first week of treatment, an effect to which the subject becomes tolerant to rapidly. During the initial phase of benzodiazepine treatment, subjects are

advised not to drive given the impairment to both cognitive and psychomotor coordination caused by benzodiazepines. These cognitive impairments are a sustained feature of chronic benzodiazepine treatment with memory function being notably affected. Patients taking benzodiazepines can also encounter paradoxical behavioral responses such as increased aggression, uncharacteristic behavior, acute rage episodes, and intermittent crying. In autistic children, paradoxical anxiogenic effects have been reported. These paradoxical effects are not unique to benzodiazepines and usually resolve spontaneously after a week of treatment or following dose adjustment. Other undesirable side effects associated with benzodiazepine use include weight gain, skin rash, menstrual irregularities, impairment of sexual function, and respiratory depression. Rare side effects such as blood dyscrasias are also sometimes seen.

Short Description or Definition

Seizures (sometimes called epileptic seizures) are the stereotypical clinical manifestations (signs and symptoms) of excessive and/or hypersynchronous, usually self-limited, abnormal activity of neurons situated in the cerebral cortex. Epilepsy is defined as two or more unprovoked afebrile seizures (Commission on Classification and Terminology of the International League Against Epilepsy [1981](#)).

Categorization

Although children with autism and epilepsy have many types of movements, the clinical

semiology of *seizures* is similar to those in children without autism (i.e., children with pediatric epilepsy alone). The most common type of seizures during childhood, a *partial seizure*, occurs in two categories. *Simple partial seizures* are those in which the first clinical signs and electroencephalographic (EEG) signatures initiate focally in one area of the brain without impairment of consciousness. Simple partial seizures show focal neurological signs such as focal jerking of one hand/arm, sensory change or pain in one limb, or a unilateral contraction of the face. *Partial complex seizures* (*psychomotor seizures*) are the more common of two types of partial seizures that manifest as focal neurological signs plus impairment of consciousness. Commonly, for instance, in temporal lobe epilepsy, patients may experience a gustatory sensation, rising epigastric feeling, or some other aura followed by a behavioral arrest. The child does not respond and stare off. Then the patient is tired. Sometimes the children develop jerking movements of limbs contralateral to the seizure focus. *Secondary generalization of partial complex seizures* occurs when seizures spread to the opposite hemisphere and is manifested clinically as *generalized tonic-clonic seizures*.

Clinical Expression and Pathophysiology

Partial epilepsies in childhood with autism often manifest as a frontal lobe or temporal lobe epilepsy. The interictal epileptiform activity until age 10–11 years is unilateral focal or multifocal epileptiform discharges. The ictal manifestations on EEG usually include evolving focal sharp-wave or spike and slow-wave discharges. As children become older (age 10–11 years), epileptiform discharges on EEGs are more frequent in the frontal or centrofrontal regions. Adolescents can have multifocal epilepsy in which the predominant seizure type is a partial complex seizure. However, a majority of seizures in the adolescent are generalized seizures. The generalized tonic-clonic seizures are the most common type of generalized seizures. The seizure may have a prodrome in which a change in behavior

is seen. Most seizures began without warning when the patient falls to the floor, cries out, eyes roll back in the head, and the limbs have a rhythmic tonic-clonic-tonic pattern of jerking. The patient may lose bowel or bladder function at the end of the ictal phase. Cyanosis can develop but is usually transient. The generalized tonic-clonic seizures are typical of frontal lobe epilepsy which occurs in adolescents. The EEG correlate is a buildup of low-voltage fast activity which evolves into high-amplitude spike/poly-spike or polyspike and wave discharges. Patients are typically sleepy or confused for some period of time after the seizure.

The second most common type, *absence seizures*, is characterized clinically by lapses in consciousness in which one can see a motionless stare, eyelids may droop, or eyes may briefly roll backwards and lasting 10–15 s in children with autism. The children usually resume their full activity after the spell or maybe briefly confused (<30 s). Only rarely, absence seizures are associated with other activity including automatisms, brief clonical movements of arms or eyelids, or loss of postural tone. The onset of absence seizures is associated with EEG onset of regular bilaterally frontal predominant generalized 3-Hz spike and wave discharges which begin and end suddenly in the setting of the background EEG for the child. With either absence or GTC seizures, children can have fragments of discharges interictally which include bilaterally frontal predominant generalized spike and slow-wave discharges.

Atypical absence seizures are lapses in consciousness in which one can see a motionless stare but are associated more with motor signs, particularly changes in tone, and can be more pronounced than in typical absence seizures. These seizures can have monitor focal or lateralizing signs. The onset and cessation of these seizures are less clear and last longer, typically 15–60 s with variable postictal confusion. These patients are more likely to have absence status epilepticus. The clinical onset is associated with similar generalized spike-wave discharges but usually at a frequency of <2.5 Hz. Although atypical absence seizures can be seen in the setting

of Lennox-Gastaut syndrome, these seizures are rarer in autism patients with Lennox-Gastaut syndrome.

Tonic and atonic seizures are more common in autism patients but not necessarily always associated with Lennox-Gastaut syndrome. *Tonic seizures* are more common in childhood and represent a continuum of the atonic-tonic seizures. The seizures have tonic spasms of the face or chest/trunk with tonic flexion of the upper extremities and flexion or extension of the lower extremities. Along with impairment of consciousness, patients can have papillary dilation, tachycardia, apnea/cyanosis, and urinary incontinence followed by a period of post-ictal confusion. Ictal EEG is low-amplitude very fast activity. Atonic seizures (usually called drop attacks) consist of a sudden loss of postural tone. In some patients, the drop attacks are preceded by one or more clonic jerks. In mild forms, the child may just have a head drop. In severe forms, the patient's whole body may drop to the floor and require a seizure helmet. The atonic seizure usually lasts only a few seconds and has little postictal period. An occasional patient may be out several minutes on the floor. Atonic seizures on the ictal EEG exhibits either generalized polyspike and wave discharges or a sudden electrodecrement (suppression) of the EEG. The synchronization of discharges between hemispheres is important for these seizure types because a corpus callosotomy can be a treatment to abolish these seizures.

Myoclonic seizures (epileptic myoclonus) are relatively rare in autism and usually seen in the most profoundly affected autism-epilepsy patients. The broader term myoclonus refers to certain quick involuntary muscle jerks involving any part of the neuroaxis. Myoclonic seizures in autism can be differentiated both semiology wise and neurophysiologically from movement disorders, hyperreflexia, and rare cases of spasticity. Myoclonic seizures (although can be unifocal, multifocal, or unilateral) are usually bilateral generalized jerks which are either sporadic or rhythmic in nature. Action or sensory

myoclonus rarely occurs in autism-epilepsy patients. Commonly, the myoclonic seizures are rapid rhythmic bilateral synchronous jerks (2–8 Hz) of the upper extremities with occasional lower extremity/whole body involvement. The ictal EEG is generalized polyspike and slow-wave discharges associated with the quick jerks.

Status epilepticus is commonly defined as repeated seizures/events without a return to consciousness lasting longer than 30 min in duration. Most types of epileptic seizures can be manifested as status epilepticus. The two major types of status epilepticus, generalized convulsive status epilepticus (major motor seizures, recurrent generalized tonic-clonic convulsions) and nonconvulsive status epilepticus (recurrent nonconvulsive seizures including absence status, partial complex status, and simple partial status) are recognized clinically. Convulsive status epilepticus is the most common medical emergency from neurological disease in autism because brain damage and death can result from the systemic consequences of repeated generalized tonic-clonic seizures. Most persons with generalized tonic-clonic status epilepticus have localized cerebral disturbances as a cause and therefore have secondary generalized partial seizures. Repeated cerebral epileptic activity can disrupt brain structures or otherwise cause permanent neurological or intellectual deficits.

Evaluation and Differential Diagnosis

See ► [“Neurologist.”](#)

Treatment

Therapy must be directed at suppressing all ictal activity on EEG. Ictal EEG activity can have a progression from (1) discrete seizures, (2) merging of seizures with waxing and waning of amplitude and frequency with variable locations, (3) continuous ictal activity, (4) continuous ictal

activity intermixed with periods of isoelectric EEG, and (5) the PLEDS or GPEDS pattern. The recurrence of frequent generalized tonic-clonic seizures in a row creates a life-threatening systemic condition of hyperpyrexia, failure of cerebrovascular autoregulation, acidosis, and severe hypoxia, causing hypotension, hypoperfusion of the brain, pulmonary edema, electrolyte disturbances, and eventual circulatory collapse. Even after cessation of status epilepticus and correction of systemic abnormalities, sepsis from aspiration pneumonia can be late but life-threatening complication of status epilepticus. Treatment of status epilepticus in autism, consisting of ABC's, correction of glucose/electrolyte disturbances, control of BP, and oxygenation, benzodiazepines, and a series of routine anticonvulsants, is not different from treatment of status epilepticus in other conditions.

Selective Attention

Bertram O. Ploog

Definition

Selective attention refers to the ability to pay attention to a limited array of all available sensory information. Selective attention, as a filter to help prioritize information according to its importance, is adaptive. If attention is too selective, however, it is maladaptive. Excessively selective attention has become known as “stimulus overselectivity,” which is prevalent in autism. Its cause or causes are assumed to be brain-organic. Because overselectivity has serious implications for impairment of learning at many levels, including social, emotional, and language learning (all key features of autism), it is suggested that an evidence-based treatment should focus on the normalization of attention patterns as early as possible to take advantage of the young brain's plasticity. Behavior analysis can provide such evidence-based treatments. Until a true cure for autism is found, behavior analysis remains the treatment of choice.

Historical Background

The term of “stimulus overselectivity” was coined by Lovaas et al. (1971) in their pioneering study investigating abnormal attention patterns in children with autism. Even though some degree of selectivity in attention is considered adaptive, Lovaas et al. (1971) felt that the degree of selectivity observed in their study was excessive, thus their term “overselectivity.” In their study, children with autism, with mental retardation, or

with typical development were first trained with so-called compound stimuli comprising visual (flood light), auditory (tone), and tactile (blood-pressure cuff) stimulus components that were presented simultaneously at predictable time intervals – in effect adding a fourth, temporal, component. When the child responded in the presence of the compound stimulus, a reward was given but not when the child responded in the absence of it. (Technically speaking, this constituted a successive discrimination paradigm.) During testing, the stimulus components were then presented successively in isolation and random order. The question of interest was whether the children would respond to the isolated stimulus components, after they had responded reliably to the compound stimuli. Generally, the typical children responded to all three isolated components, the children with mental retardation to two, and the children with autism to only one. (No child responded to the temporal element.) Thus, the children with autism were more selective in their attention to isolated stimulus components than the children in the other two groups. No consistent preference for any particular sensory modality was observed for these three groups.

Over the next four decades, this study by Lovaas et al. (1971) has stimulated a slew of follow-up research studies that employed a variety of different training and testing paradigms, different sensory modalities and stimulus types, and various schemes of experimental control and matching procedures (e.g., by diagnosis, chronological age, mental age, verbal skills, functioning level, and severity of autistic traits). No consistent pattern has emerged though (cf. Ploog 2010). For example, even though stimulus overselectivity is clearly prevalent in autism, it also occurs in other diagnostic categories (e.g., Down Syndrome); even though there appears to be a correlation between mental age and degree of overselectivity, there is evidence that overselectivity is also independent of mental age; and even though overselectivity is more likely to occur with increased stimulus complexity, overselectivity can also be shown in relatively simple two-stimulus situations. In some cases, it can even

be shown that the atypical attention consists of a *lack* of focus and *not of too narrow a focus*. In other words, processing of sensory information appears simply disorganized or haphazard and quite the opposite to the original conceptualization of overselective attention. Despite such inconsistencies, however, there is consensus that children with autism somehow differ from their typically developing peers in their attention patterns. This has lead researchers to propose different conceptualizations of attention patterns in autism, which will be discussed in the following section. After that, the implications of atypical attention patterns will be discussed. Finally, possible treatment approaches to remediate or normalize such atypical attention patterns will be discussed.

Alternative Conceptualizations

Table 1 is an attempt to provide a way to compare and delimit several of the most common

Selective Attention, Table 1 Comparison of theories in their conceptualizations of atypical attention patterns in ASD

	Approach			
Regarding atypical attention, the theory/ hypothesis . . .	SO ^a	PD ^b	WCC ^c	PPF ^d
distinguishes between local versus global information	x	x	x	x
assigns a role to “meaning”		x	x	
assumes bias/ undirected focus rather than true deficit	x	x	x	
sees atypical attention as cause for other abnormalities	x	x		
posits diminished movement perception				x
attempts to account for all sensory modalities	x	x	x	

^aStimulus Overselectivity Hypothesis

^bPrioritization Deficit Hypothesis

^cWeak Central Coherence Theory

^dEnhanced Perceptual Functioning Theory

approaches to understanding the atypical attention patterns seen in autism: stimulus overselectivity hypothesis, prioritization deficit hypothesis, weak central coherence theory, and enhanced perceptual functioning theory. The stimulus overselectivity hypothesis (SO) was introduced in the previous section.

The prioritization deficit hypothesis (PD) is really an extension of SO, except that instead of limiting the attentional abnormalities strictly to “overselectivity,” it includes unfocused, unattended, misdirected, or chance attention to isolated stimulus features. This extension seemed justified based on studies that implied that, surprisingly, the attention of children with autism was *less* selective than that of typically developing children. In Ploog et al. (2009), for example, children with autism and with typical development were shown to accurately discriminate between spoken sentences on the basis of *what* was being said (content) and *how* it was being said (prosody: question vs. statement). So there was no deficit in perception or attention. However, when content was pitched against prosody, the autistic children chose both, content, and prosody, with equal probability whereas typical children focused their attention strongly on content. (There was some evidence, albeit not statistically significant, that the children with autism slightly outperformed the typically developing children on prosody discrimination.) Such a finding of reduced selectivity does not seem to be restricted to language stimuli (e.g., Ploog and Kim 2007, with tactile stimuli, even though a point was being made in their study that, depending on interpretation, the children with autism did in fact exhibit restricted attention). In the language study in particular, it appeared as if the children with autism, in the context of testing, indiscriminately responded to any stimulus dimension whereas the typical children assigned higher priority to content, even though all children were perfectly capable of perceiving differences in both content and prosody. In other words, the children with autism did not prioritize the information embedded in the stimuli according to what seemed to be the most relevant information to the typical children – such prioritization being an

example of *adaptive* selective attention. Thus, PD essentially broadens the SO notion to encompass maladaptive undirected attention. Early work by Etzel et al. (1981) raised the notion of “relevancy” in the development of stimulus control, which is a behavior analytical term to operationalize “attention” (e.g., Reynolds 1961). In PD, this concept of “relevancy” incorporates the notion of “meaning” when responding to language stimuli. The children with autism appear to select their choices of stimulus components more on a sensory-perceptual basis, whereas the typical children do so based on a higher cognitive level. This hypothesis was put to a test in a series of studies by Ploog and colleagues (Brooks et al. 2018; Brooks and Ploog 2013; Ploog et al. 2014). The findings were mixed. For example, in Ploog et al. (2014), we used the same test paradigm as Ploog et al. (2009) but employed German speech stimuli with participants who did not speak or understand German. The rationale for using “unfamiliar” speech stimuli was to remove “meaning” for both the typically developing and the autistic children. However, overall, the typical children still continued to prioritize content over prosody. Another interesting finding was provided by Brooks and Ploog (2013) who employed affective stimuli: the preference for content versus prosody was moderated by the emotional valence. “Grouchy” stimuli made typically developing children decrease their preference for content (as if they avoided the negative tone) whereas “enthusiastic” stimuli made children with autism increase their preference for content (as if they were more attracted by the positive tone but ignored the negative tone). Brooks et al. (2018) found that children with autism did not exhibit a deficit in generalizing to an unfamiliar voice (from training male to testing female or vice versa). However, note, that all four studies showed clearly that there was no bona fide deficit in perception in the children with autism.

Another conceptualization of atypical attention in autism is captured in the weak central coherence theory (WCC; e.g., Happé and Frith 2006). The main idea of WCC is that the “cognitive style” in autism is to perceive and process sensory information in a “detail-focused” manner rather

than to integrate an array of information in a larger context. As such, WCC is consistent with SO. In contrast, however, WCC is based on the assumption that a deficit in central coherence leads to a failure to extract “meaning.” SO does not afford a special status to meaning per se, beyond the overall information that is embedded in the stimuli, whereas PD, as was discussed above, does not posit that atypical attention results in a failure to extract meaning but rather that a failure to extract meaning results in atypical attention. Happé and Frith (2006) pointed out three challenges to early accounts of WCC: First, WCC may result (but not necessarily so) in superior processing of some information possibly because of the sharper focus on local information and because of the exclusion of global, contextual, and semantic information, which might distract from a sharp focus on local information. SO is compatible with this notion; PD is, too, as a chance focus on some stimulus feature or piece of information may result in superior processing of it. This idea may explain the underlying mechanism of the “savant” phenomenon that has been reported in some, albeit rare, cases of autism. Second, WCC may be a bias in selecting some information rather than a true deficit of not attending to certain aspects of sensory information. This, again, is compatible with SO and PD as it has not been possible to show in the literature any modality-specific deficits or limit to the degree of complexity to account for atypical attention. Third, WCC may be a by-product rather than the cause for anomalies in social cognition. In contrast, SO and PD both provide convincing evidence that atypical attention may be the cause for a multitude of deficits seen in autism, without arguing that atypical attention is the cause for autism. In this respect, SO and PD are not compatible with WCC.

Enhanced perceptual functioning (EPF; e.g., Mottron et al. 2006), as the name implies, posits superior perception in individuals with autism compared to typically developing individuals. Superiority in perception is assumed to occur in both, “low-level” and in “complex” cognitive tasks. In elaborating on EPF, Mottron et al. (2006) proposed “eight principles of autistic

perception.” The three most important ones are: First, an enhanced detail perception is assumed. This puts EPF on equal footing with SO, WCC, and PD and can possibly account for superior perception in some areas. Second, EPF proposes diminished movement perception. None of the other theories considered here speak to this issue directly; it is also not clear how this notion might be linked to atypical attention with respect to information that is not characterized by movement per se (e.g., language, tactile perception, and still pictures of visual patterns). However, if one considers movement information as just one specific type of information, SO, WCC, and PD can account for diminished movement perception, just as for any other form of compromised information processing. Third, autistic individuals exhibit increased frequency of lateral glances—a behavior that may be involved in perception of movement. Again, it is not clear how lateral glances would be critical in the development of attention to information other than the visual modality. The other theories considered here do not address this behavior. In conclusion, it seems that EPF is focusing on visual attention, whereas the other theories can incorporate attention within all sensory modalities.

Implications for Autism Spectrum Disorders

In the following discussion of the implications of abnormal attention in autism, the focus will be on a limited selection of key characteristics of autism: impairments in social skills, language, and emotional behavior. In addition, a hypothesis with regard to a contributing cause of stereotypic behavior, also common in autism, will be proposed.

Assuming that a child with autism is not attending to contextual and situational information in the same manner as a typical child would, it should not be surprising if a number of problems develop as a result. Consider a situation in which a child with autism, Andy, would like to play soccer with another child, Brad. Andy sees the ball, likes it, runs towards it, and tries to kick it. But he may not have heard what Brad said

because his attention was on the ball, not on other contextual and situational information. Whether Brad said, “Hey, go away! I am waiting for my friend to play with!” or “Hey, that’s great! You like soccer, too! Let’s play!” represents a critical difference in the way Andy would experience the conclusion of this social interaction. In the first case, Brad would probably take the ball away from Andy and show anger or worse. In the second case, Brad might let Andy have the ball and try to play with him. From Andy’s perspective, however, it was impossible to predict what he was going to experience. In one case, the soccer ball will be associated with a pleasant social interaction, in the other case with an unpleasant one. Of course, a social situation does not rest on one piece of information (i.e., the soccer ball) but also on a multitude of other cues (e.g., what is being said, how it is being said, “body language” of the other person, facial expressions, whether only one additional person or several persons enter in the social situation). Even if Andy attended to some of the spoken language (e.g., “Hey”), it would not have been sufficient to allow Andy to negotiate the social interaction with Brad. Under these considerations, it should be obvious that Andy would be very unlikely to develop normal, social behavior.

The previous scenario may also serve as an example to discuss the development of appropriate emotional behavior. Brad may have said “Hey” while smiling or frowning. If Andy was indeed oblivious (not paying attention) to the different facial expressions, he would have missed out on an opportunity to learn that happy and angry faces, displayed by others, are usually correlated with running into an emotionally positive or negative situation, respectively.

Abnormal attention much earlier in life represents an even bigger problem: At birth, most children nurse reflexively but the efficiency with which they do so is subject to learning as the mother provides important feedback for effective suckling. Furthermore, whether the baby nurses correctly or perhaps bites the mother’s nipple produces different consequences. In the former case, the mother might rock the baby, hum soothingly, and the baby is naturally rewarded with milk.

In the latter case, the mother might yelp in pain, push the baby back, say “No!”, and nursing is interrupted. Typical children learn the consequences of their behavior quite early, readily, and quickly. (A 2-month-old or even younger baby, for example, can learn to move his limbs in order to make a mobile spin.) But learning the consequences of one’s behavior depends critically on attending to a number of cues (e.g., tasting milk in mouth, hearing “no” or the soothing humming, feeling being pushed back, or being rocked gently). If a child does not attend to a variety of cues, the direction of any social interaction will be unpredictable and it will not develop appropriately.

Acquisition of language depends critically on being able to attend to multiple cues as well. Either overselective attention (SO and WCC concept) or unfocused, undirected attention (PD concept) would result in an impairment of language development. In the example of the nursing baby, it should be obvious that the baby will not learn the meaning of “no” as a verbal cue not to repeat whatever the baby was doing before hearing “no.” (Technically speaking, this is an example of positive punishment.) Here is another example: An infant is on a stroll with his mother. The mother is pointing out a cat and says: “Look at the kitty!” A little bit later, they come across a dog and the mother says: “There’s a doggie!” An infant, who pays attention only to the dog and cat animals but not to what the mother says, will not acquire the correct labels. Maybe the infant is not even looking at the animals but instead at the parked cars or the trucks at a construction site next to the sidewalk. But even if the child was attending to the animals *and* to his mother’s speech, it would be possible to learn the proper labels only if the infant actually attends to the relevant sounds (i.e., “doggie” and “kitty”) in his mother’s speech. Such language learning can be explained well by so-called “statistical learning” (which is the term used by linguists to refer to language learning through classical conditioning; Pavlov 1927) but it only works if the listener is able to detect the sequential patterns of sounds in speech (e.g., “the” and “a” being followed with high probability by a noun referencing an

object in the listener's environment). Finally, with critical deficits in receptive language (i.e., listening), one would expect that development of expressive language (i.e., speaking) would be seriously compromised.

With all these examples, one can appreciate that the child, who suffers from abnormal attention (either not being able to process several paths of information simultaneously or not being able to focus on the relevant piece of information), lives in an essentially unpredictable world. Learning in general is severely impaired; social interactions cannot be understood; whatever happens as a result of one's actions is not predictably linked to one's own behavior; language is a meaningless garble of sounds instead of probabilistic patterns; and other people's emotions – with significant consequences for self – will appear random. At the same time, good and bad things will happen to the child without much chance to understand why. Experimental work (as early as Pavlov 1927) has shown that unpredictable consequences to one's behavior, or random sequences of events that occur independently of one's behavior, might result in erratic and bizarrely stereotyped behavior (experimental "neurosis," Pavlov 1927, or "superstition," Skinner 1948). Abnormal attention and the resulting unpredictable consequences and events may therefore contribute to stereotyped behavior that is quite common in autism. (This is not to deny the possibility that engaging in these stereotyped behaviors, such as self-stimulatory behavior, are in itself reinforcing to the child, either because of the sensory stimulation it provides or because of the child's ability to produce some predictable outcome.)

Treatment Based on Normalizing Attention Patterns in ASD

WCC and EPF do not directly suggest treatment or remediation strategies. SO and PD do. This is so because both SO and PD base their analyses on operational definitions of attention that then allow the atypical attention to be normalized directly. There are no claims that any of these treatments result in a removal of the original

cause of abnormal attention or other deficiencies (whether such deficiencies are secondary to abnormal attention or not). Rather, remediation strategies should be seen as "crutches" to overcome some of the abnormalities in a given situation. However, if remediation strategies are implemented from early on, chances are that the brain, when it still has great plasticity, can be trained to process information more adaptively despite putative brain-organic differences compared to the typical brain. At the very least, the rate of divergence between typical and abnormal attention and problems resulting from abnormal attention can be minimized while the autistic child is developing. (Note that *despite effective* treatment, IQ scores may still decrease just because the rate of increasing mental age and cognitive functioning, due to effective treatment, is not keeping pace with the rate of increasing chronological age.)

Some behavior analytical treatments focus specifically on so-called pivotal behaviors such as attention to multiple cues (Koegel et al. 1989). Pivotal behaviors are behaviors that once acquired result in changes in other behaviors even if those were not specifically trained. Training of pivotal behaviors is therefore a very efficient way of producing significant, positive, and broad behavior changes without having to train each target behavior individually. Responding to multiple cues is considered a pivotal behavior because an ability to simultaneously pay attention appropriately to multiple bits of information is the basis for learning almost anything (as alluded to before). Pivotal behavior training for changing a person's attention to multiple cues is based on the conceptual framework of SO, which can easily be expanded to incorporate PD accounts of situations when attention seems to be directed towards irrelevant cues – cues that should be low in priority for attention – and not to high-priority cues. Two strategies will be discussed: attentional shaping (also referred to as within-stimulus fading or transfer-along-a-continuum) and training on conditional discrimination tasks.

Sidman and Stoddard (1966) conducted a pioneering study to demonstrate the effectiveness of attentional shaping – resulting in attention to a

neglected aspect of a stimulus – by employing drawings of ellipses with varying widths that children with mental retardation initially found very difficult to discriminate. Attentional shaping is a fading procedure that focuses the child on a relevant stimulus dimension from the very beginning of learning a difficult discrimination task (e.g., the width of the ellipse) by first exaggerating the difference and then decreasing it gradually. Ploog and Williams (1995) conducted a pigeon study to assess theoretically the effectiveness of this procedure and contrasting it with another procedure using so-called extra-stimulus prompting (Schreibman 1975) and a trial-and-error procedure. The following serve as an example for attentional shaping: It may be difficult for a child with autism to learn to tell apart the letter “E” from the letter “F,” if the child only attends to any features of the letters other than the critical one – presence or absence of the horizontal line on the bottom of the letters. Attentional shaping would begin with drawing the child’s attention to the feature that is critical for distinguishing between the two letters (i.e., bottom horizontal line). A first step might involve presenting sequentially flash cards with either a big horizontal line on it or a blank card with nothing on it. Once the child mastered this first step (generally not a difficult task even for a child with atypical attention), the next steps are introduced. The exaggerated line is gradually reduced to realistic dimensions and moved towards the bottom of the flash card. Then, the letter “F” is faded in on both flashcards until both letters are presented realistically (“E” being “F” with line vs. “F” being “F” without line).

Advances in computer technology have made attentional shaping much more feasible – especially if embedded in a fun computer game – because the different steps in training can be automated and individually titrated (including correction procedures) while the child is enjoying playing a computer game. Attentional shaping can be implemented in any situation as long as the distinguishing (relevant) feature of a discrimination task can be identified. An alternative way of teaching a difficult discrimination task, but possibly more problematic and not based on

attentional shaping, is what is commonly called “prompting.” Applied to the previous example, the adult may point to the letter “E” and reward the child for saying “E” or for selecting it from several choices. Then the prompt (i.e., the pointing finger) may gradually be removed. The reason why such prompting may not be so effective with a child who does not attend to multiple cues is that the child may only attend to the pointing finger but not simultaneously to the finger *and* the letter “E.” The failure to learn about the relevant stimulus feature can be explained by the behavior-analytic concept of “stimulus blocking” (e.g., Ploog and Williams 1995). Intuitively, such failure is also not surprising because the child is probably unresponsive to multiple cues to begin with, thus will either not attend to the pointing finger or not to the letter “E.” The two techniques, attentional shaping and prompting in the manner described here, have been referred to as within- and extra-stimulus prompting (cf. Schreibman 1975, who also showed superiority of within-stimulus over extra-stimulus prompting). Generally, the attentional shaping approach has been more effective than other prompting techniques in teaching children with autism because it practically imposes from the very beginning the stimulus feature that was initially neglected or was not given attentional priority by the child. By conducting extended training with attentional shaping methods, the child can learn the pivotal behavior of responding to multiple cues, that is, acquire a generalized skill beyond simply learning a series of individual discrimination tasks (Stokes and Baer 1977).

The learning of conditional discrimination tasks poses major difficulties to children who are not responsive to multiple cues. However, extended training on these task results in a generalized, increased responsiveness because learning to attend to multiple cues is inherent in the task by implicitly providing reinforcement only for attending to multiple cues. Consider this example: A mother might say “Please, pick the red shirt and get dressed!” or “Please, pick the blue pants and get dressed!” Unless the child paid attention to color and the particular clothing item, the child would have difficulties to follow the mother’s

request and not earn praise. A training procedure to make the child attentive to multiple cues can be implemented conveniently on a computer. For example, the words “RED SHIRT” might flash on the screen (or a person or computer could present the spoken words). After a short delay, pictures of several items will be given as choices to the child: a red shirt, a blue shirt, red pants, and blue pants. If the child picks the correct item (i.e., red shirt), he earns a reward such as a point, later to be exchanged for some preferred activity, or being allowed to view a brief, engaging video clip. Training would proceed with many of similar stimulus sets. Responsiveness to multiple cues can easily be expanded to incorporate three, four, or more cues (e.g., red/blue, big/small, new/old, corduroy/canvas, pants/shorts). Finally, it should also be clear that conditional discrimination tasks can be incorporated in daily life without requiring explicit training sessions with the associated advantages (e.g., more enjoyable for the children; logistically more convenient for the parents than having to schedule separate therapy sessions; more affordable and efficient because therapy can be implemented 24/7). Thus, providing conditional discrimination training should be part of parent training by using daily life situations (e.g., red/blue shirt/pants when getting dressed; small/big spoon/fork when setting table; blue/white small/large frisbee/ball).

Summary

Selective attention is adaptive, but if it is too selective, disorganized, or undirected, it is considered an abnormal attention pattern that is maladaptive. Abnormal attention is prevalent in autism but not specific to autism. Abnormal attention has been conceptualized as stimulus overselectivity, a prioritization deficit, weak central coherence, or enhanced perceptual functioning. Regardless of conceptualization, abnormal attention has serious implications for normal functioning and learning deficits, including many of the landmark features of autism such as deficits in language development, social and emotional behavior, academic success, abstract

cognition, and even possibly stereotypic/self-stimulatory excessive behaviors. Therefore, treatments should focus on normalizing attention patterns in individuals with autism as early in life as possible. Because the ability of normal selective attention is considered pivotal, behavior analytical treatments have targeted a normalization of attention in individuals with autism. As a treatment, attentional shaping is effective in training to direct attention specifically to one or several aspects of the surroundings that were previously neglected. Training on a series of conditional discrimination tasks is effective as a treatment in increasing the overall responsiveness to multiple cues and conveniently can be implemented by the primary caregivers.

Selective Mutism

Corey Ray-Subramanian
Waisman Center, University of Wisconsin-
Madison, Madison, WI, USA

Synonyms

Elective mutism

Short Description or Definition

Selective mutism is a disorder characterized by a “persistent failure to speak in specific social

situations (e.g., school, with playmates) where speaking is expected, despite speaking in other situations” (American Psychiatric Association [APA] 2000, p. 125). The diagnostic criteria for selective mutism also require that the disturbance lasts for more than 1 month and interferes with social communication or educational or occupational achievement. Additionally, the failure to speak cannot be the result of a lack of knowledge or comfort with the language expected in the social situation. Selective mutism is also not diagnosed if the disturbance is due to a communication disorder or occurs exclusively in the context of a pervasive developmental disorder, schizophrenia, or other psychotic disorder (APA 2000).

Categorization

Selective mutism is listed under Other Disorders of Infancy, Childhood, and Adolescence in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV; APA 2000). Some scholars have argued that it would be more appropriate to categorize selective mutism under anxiety disorders in the DSM or classify it as a behavioral symptom of certain anxiety disorders rather than a distinct disorder (Anstendig 1999). Children who develop selective mutism tend to have similar biological and family dynamic characteristics as those who develop anxiety disorders, and cognitive-behavioral and pharmacological treatments for anxiety disorders have been used successfully with children who exhibit selective mutism (Anstendig 1999). However, there are currently no plans to list selective mutism as an anxiety disorder in the next edition of the DSM (APA 2010).

Epidemiology

The disorder has been estimated to occur in 0.2–2.0% of youth and tends to be more common in girls than boys (Kearney 2010). Prevalence rates are often higher in school-based samples compared to clinic-based samples because

children with selective mutism may not necessarily be referred for mental health services, as they are not disruptive in school (Cleave 2009).

Natural History, Prognostic Factors, Outcomes

Selective mutism usually develops during the pre-school years but may not be diagnosed until the child is in elementary school (Viana et al. 2009). The disorder does not have a specific, identified cause and likely develops through multiple pathways (Viana et al.). It is associated with a slow-to-warm and shy temperament (Sharp et al. 2007). Parents of children with selective mutism tend to have higher rates of anxiety and other forms of psychopathology than control groups (Viana et al. 2009). Some researchers have found relatively high comorbidity between selective mutism and other communication disorders (Viana et al.). For some children, selective mutism may have a chronic course that can lead to problems with peer rejection, academic performance, or social skills (Kearney 2010). For other children, the disorder may only last a few months (Sharp et al. 2007). Adults are less likely to be diagnosed with selective mutism, probably because they have more control over their environment and can more easily avoid situations that require speaking (Sharp et al.). Many young adults who were diagnosed with selective mutism as children report difficulties with self-confidence, independence, achievement, and social communication skills (Sharp et al.).

Clinical Expression and Pathophysiology

The clinical expression of selective mutism is usually characterized by a child who speaks normally at home with family members and does not speak in other settings, such as school or restaurants. Many children with selective mutism will also present with symptoms of anxiety disorders, particularly social phobia, which may include

fearing and/or avoiding social or performance situations. Parents, teachers, and peers may compensate for the child's failure to speak by speaking for the child or allowing nonverbal forms of communication (Kearney 2010).

The pathophysiology of selective mutism has not been directly examined, although physical symptoms of anxiety (e.g., increased heart rate, shaking, sweating) may be present in some individuals with selective mutism (Kearney 2010).

Evaluation and Differential Diagnosis

Evaluations for selective mutism may begin with interviewing the child, his or her parents, and the child's teacher. Some children with selective mutism will respond nonverbally (e.g., shaking head) to yes/no questions, which can provide an opportunity to obtain information from the child's perspective (Kearney 2010). Interviews may include questions related to each of the specific diagnostic criteria for selective mutism, the settings that involve a failure to speak, the circumstances surrounding the failure to speak, whether the child can be encouraged to speak in certain public settings, symptoms that may surround the child's failure to speak, and how others respond to the child's mutism (Kearney 2010). Behavior scales specific to selective mutism, anxiety, depression, and oppositional behavior can also be useful for obtaining information from multiple informants. Evaluations for selective mutism can also include direct behavioral observations across settings (Kearney 2010). In terms of differential diagnosis, if there is reason to suspect that a child's failure to speak is better accounted for by a communication disorder (e.g., specific language impairment), it would be important to conduct a comprehensive speech/language evaluation.

Treatment

Interventions for selective mutism include behavioral strategies such as exposure-based practice,

stimulus fading, shaping and prompting, relaxation training, and self-modeling, as well as pharmacological treatments (Kearney 2010). Exposure-based practice involves a hierarchy of speaking situations in which the child is expected to gradually speak in increasingly difficult or anxiety-provoking situations (Kearney 2010). Stimulus fading can be incorporated into exposure-based practice by gradually introducing new stimuli (e.g., peers or teachers). Shaping and prompting involve the reinforcement of successive approximations of the desired behavior. Relaxation training focuses on teaching the child how to relax his or her muscles and breathe properly to manage physical symptoms of anxiety. Self-modeling techniques may involve videotaping the child speaking clearly at home and playing the video at school to model the desired behavior in a setting in which speaking does not currently occur (Kearney 2010). The research base on pharmacological treatments for selective mutism is somewhat limited, but selective serotonin reuptake inhibitors (SSRIs) have shown promise for treating cases of selective mutism that are not responsive to psychosocial or behavioral interventions (Carlson et al. 2008).

Self-Advocacy

Christie Enjey Lin
Departments of Education and Psychiatry, Child and Adolescent Psychiatry, University of California, Los Angeles, CA, USA

Synonyms

Advocacy; Autonomy; Efficacy; Independence; Self-determination; Self-direction; Self-empowerment; Self-reliance

Definition

Self-advocacy refers to the skills of people from within a specific group to integrate knowledge

about their civil rights, relevant laws, and their relative adaptive strengths and weaknesses to effectively communicate their perspectives and needs to the overall community (on an individual level to broader social systems). With regard to autism spectrum disorders (ASD), self-advocacy movements developed in reaction to the impingement of civil rights experienced by people with developmental disabilities (Ward and Meyer 1999). A few advancements that have arisen from these movements include integration with mainstream society, access to education and independent living, and, overall, being recognized as a full and equal member of society. Contemporary notions of self-advocacy refer to people on the autism spectrum (including their families and caregivers) using and developing skills to effectively communicate their overall needs from personal (e.g., a student expressing a need for classroom accommodations to the teacher) to broader social issues (e.g., groups of people with ASD collaborating with organizations and lobbying to develop public policies to prevent discrimination; Turnbull and Turnbull 1985).

Self-advocacy requires complex organizational skills (e.g., personal decision-making, goal-setting) and understanding of social institutions (e.g., navigating the political system). These skills are seen as crucial to developing a strong sense of agency and empowerment within the ASD population. Direct training in self-advocacy to promote active life participation has been proposed by some as an integral aspect of improving the lives of people with ASD that should begin at a young age (Shogren and Turnbull 2006). In particular, receiving opportunities to make informed choices and exercise decision-making is regarded as the foundation for self-advocacy (Turnbull and Turnbull 2001). Some have also argued that self-advocacy requires direct instruction (e.g., workshops) and guided experience to develop necessary skills and enter related leadership roles (Caldwell 2010). It should be noted that there is some tension between notions of self-advocacy that involve disclosure of an ASD diagnosis to others (Davidson and Henderson 2010) and concepts of social inclusiveness that disparage the use

of labels as a means of oppression and social control (Bagatell 2010).

Self-Care

Arlette Cassidy

The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

Self-care is a subset of adaptive skills and activities of daily living that encompass (a) eating/feeding/drinking, (b) personal hygiene/grooming, (c) toileting, and (d) health/medication management. Many individuals with autism need systematic, intensive teaching in self-care skills due to

deficits in language and attention skills, interfering behaviors, and/or sensory impairments. Teaching self-care skills should occur naturally during daily routines, in all environments. Assessments are done to determine current abilities, strengths, and likes as well as frustrators and limitations. Targeted skills may be designated by participants of an interdisciplinary team. A longitudinal and functional approach should be taken when planning a self-care skill program. The steps for each self-care skill need to be broken down and clearly defined: (a) specifying the target skill, (b) task-analyzing the skill, (c) systematically instructing the skills training, (d) evaluating progress of the learner, and (e) making program modifications as needed. To teach effectively, it is helpful to define the style in which the individual with autism learns best, whether it is visual, sounds, words, touch, and/or smell. The instructional design should also consider the use of physical and verbal cues, behavioral support, generalization and maintenance, and reinforcement.

Techniques to Assist in Learning Self-care Skills

Visual Aids

Remember kids on the autism spectrum usually learn better with both visual and verbal information. Try very simple illustrations using stick figures and show the step-by-step actions. While we take getting dressed for granted, putting a shirt on is actually a long sequence of complicated movements for any young child. Break the process into its smallest components and illustrate each one. For example, step-by-step illustrations for putting on shoes, brushing teeth, and toileting can be stuck to the relevant wall for your child to follow. You can tap each picture to prompt your child on each step.

Social Stories™

Try using these illustrations in a social story, a powerful technique for learning new skills. Social stories are an excellent way to introduce the

concept of a new skill, especially when a child dislikes disruption to routines.

Applied Behavior Analysis

One of the most effective interventions for autistic disorders is applied behavior analysis. It uses a simple ABC model for learning new behaviors:

- Antecedent – a request by the parent or therapist
- Behavior – the child's response (or lack of response) to the request
- Consequence – what happens as a result of the behavior, i.e., praise for success

First, the skill to be learned is broken down into the smallest units for easy learning. For example, a child learning to brush teeth independently may start with learning to unscrew the toothpaste cap. Once the child has learned this, the next step may be squeezing the tube, and so on.

Self-Contained Classroom

Trina D. Spencer

Rightpath Research and Innovation Center,
University of South Florida, Tampa, FL, USA
Institute for Human Development, Northern
Arizona University, Flagstaff, AZ, USA

Synonyms

[Life skills classroom](#); [Separate classroom](#); [Special education classroom](#)

Definition

The term “self-contained classroom” refers to a classroom, where a special education teacher is responsible for the instruction of all academic subjects. The classroom is typically separated from general education classrooms but within a neighborhood school. A self-contained classroom is a special education placement that falls near the middle of a continuum of program options that range in restrictiveness, where the general education classroom is least restrictive and a hospital or a homebound placement is most restrictive. Student-to-teacher ratios in self-contained classrooms are usually smaller than in general education classrooms and other less restrictive special education placements such as resource classrooms. Children who are placed in self-contained classrooms often have multiple, intensive support needs and require a comprehensive and highly structured educational and/or behavioral program. Children who receive the majority of their instruction in self-contained classrooms may be

integrated with their peers for music, physical education, and art classes. Even though the concept of self-contained classrooms was derived from the Individuals with Disabilities Education Act (IDEA), there is no federal definition of self-contained classroom, and the term is not mentioned in the law.

Self-contained classrooms have been advocated for a number of different student groups. Many students with autism receive their instruction in self-contained classrooms because these classrooms are led by teachers who have specialized training to instruct this population. Similar arguments have been made for self-contained classrooms for students identified as gifted and talented and students with emotional and/or behavioral disorders.

An alternate definition of self-contained classroom exists. In some contexts, self-contained classrooms are more broadly defined as any classroom where a single teacher teaches all subjects. This definition applies to most elementary school classrooms but is distinguished from team teaching models, where each teacher of a grade teaches a single subject to each class in rotation.

Self-Help Skills

Rebecca Edmondson Pretzel, Ashley Durkee Hester and Sue Porr

Carolina Institute for Developmental Disabilities,
University of North Carolina at Chapel Hill,
Chapel Hill, NC, USA

Definition

Self-help skills are a subset of a larger repertoire of daily living skills, sometimes called activities of daily living (ADLs). Specifically, the term “self-help” usually refers to the following basic areas of independent behavior:

- *Eating/Feeding and Drinking*: Skills may include holding and using utensils properly, drinking without spilling, eating a variety of foods, proper use of a napkin, table manners, and other mealtime routines.
- *Grooming*: This area includes skills such as brushing hair, shaving, and dressing (e.g., selecting clothing, putting clothes on and off without assistance, and managing fasteners).
- *Personal Hygiene*: Skills include those such as bathing, brushing teeth, washing hair, and applying deodorant.
- *Toileting*: Skills related to toileting include managing clothing, cleaning oneself, as well as overall bowel and bladder management.

These may be considered the primary critical skill areas in the first 10 years of life and form the foundation for other skills to follow (Anderson et al. 2007); more complex skills will be required for adolescents and adults.

Self-help skills are a set of basic skills needed in order for a person to live independently (Volkmar and Wiesner 2009) and to succeed both in work and leisure as well as socially. Individuals with autism spectrum disorders (ASD) often have difficulty acquiring self-help skills and may need targeted instruction in this area of development. Critical areas of self-help and the importance of specific skills may

fluctuate with age and setting. For example, for a young child, it will be important to focus on basic feeding, eating, dressing, and toileting skills, whereas, a child in elementary school may be focused on lunchtime routines in several environments (e.g., home and school cafeteria) and independent use of a school backpack. Puberty and the teen years bring on new hygiene and self-care issues such as using deodorant, shaving, and managing monthly menstrual periods (Sicile-Kira 2006).

As young people with ASD transition beyond the school doors and into the community, self-help skills become more nuanced. For example, a person needs to go beyond just getting dressed to making the appropriate choice of clothing for a job interview. Grooming and personal hygiene routines become skill sets tied to one's self-awareness of needs and the community/work setting.

As demands fluctuate, the professionals who are identifying and assisting with the development of these skills (e.g., educators, psychologists, occupational therapists) may be multiple and will also change over time (Anderson et al. 2007).

The attainment of basic self-help skills is critical in order for individuals to participate as independently as possible in home, community, school, and work settings. Individuals with ASDs often show significant deficits in adaptive skills relative to their age and cognitive ability, and the gap between cognitive ability and adaptive skills frequently increases with age (Minshawi et al. 2009). Specific deficits have been noted in speaking, dressing, reading, the ability to comply with requests, socialization, play skills, and toileting (Scheuermann and Webber 2002). In addition to reducing dependence on caregivers, possessing adequate self-help skills is critical for maintaining health and social acceptance (Anderson et al. 2007; Scheuermann and Webber 2002). Scheuermann and Webber (2002) identified toileting, eating, dressing, personal grooming, and hygiene as the most essential self-help skills for increasing social acceptance, noting that peer rejection is often higher if individuals appear dirty or disheveled.

Instrumental Activities of Daily Living (IADLs)

While basic self-help skills (feeding, dressing, eating, toileting, and grooming) allow a person with ASD to function more independently in the home/school setting, additional life skills beyond this realm are also essential. These skills are often referred to as instrumental activities of daily living (IADLs) and go beyond the basics of getting up in the morning, dressing, and eating breakfast. They are the skills that support life in the home and community and may demand more complex interactions than basic activities of daily living (BADLs)/self-help skills (AOTA 2014). IADL categories for consideration when looking at functional independent living may include:

- *Care of Others*: This area of IADLs includes activities such as pet care, selecting and supervising caregivers and support personnel, and child rearing. Pets in the homes of children with ASD have fostered social engagement and interactions for these youth (Autism Speaks 2015). Pet care may be a first consideration in the *care of others* realm for children and adults with ASD. As youth with ASD age, the role of self-advocacy intertwines with IADL tasks related to caregiver/support personnel.
- *Communication Management*: This area of IADLs focuses on telephone use, communication devices, use of personal digital assistants, and cellphone use. With the continuous change in the area of assistive technology (AT), these skills and devices need frequent review and assessment for effective and efficient use. Being able to advocate for one's needs in this area is also a target for intervention as a young user of these tools moves into the increasingly more digital work world. Tools such as the Student Self-Evaluation Matrix (QIAT 2018) are available to help young technology users be better problem solvers and advocates for their AT in settings beyond the high school arena.
- *Community Mobility*: While mobility in the self-help area usually refers to transfers from place to place, community mobility focuses on pedestrian mobility and public transportation use. Considerations regarding driving via

appropriate driving assessment are also included in this IADL area and are important to explore as teens with ASD transition to adulthood (Anderson and Foden 2009)

- *Financial Management*: This IADL area covers the realm from basic money use to banking and financial decision-making. Topics in this area include the ability to make financial decisions beyond those taught in the classroom setting. Persons with ASD need real-life practice in the community to acquire these skills. This area includes personal finance management as well as information on Social Security income (in the USA) and daily money handling skills for purchases and bills (VT Transition Guide – Financial) and should include understanding of relevant legislation related to financial issues (e.g., ABLE Act of 2014).

All of the above areas are related to the concepts of *self-advocacy and self-determination*. Young people with ASD need to learn to assess their own needs, be involved in decision-making on their own behalf, and demonstrate self-determination skills. Components of self-determination and self-advocacy that can be taught to persons with ASD involve skills in (1) personal goal setting, (2) choice making, (3) self-regulation, and (4) decision-making (Wehmeyer et al. 2010). Young adults with ASD need to combine all these skills to make life choices regarding self-care (managing medical needs, healthy lifestyle) and positive social interactions (e.g., community clubs, safe online social experiences).

It is important to regard these skills as important and teachable tasks for youth with ASD in the high school setting. While research in the area of evidence-based transition intervention strategies is still limited, several key findings regarding high school experiences for youth with ASD have been noted (Wehman et al. 2014). Best practices for students with ASD in high school should include more rigorous student participation in his/her transition planning, actual training in self-determination skills, paid work experiences while in high school, and involvement in student

mentoring programs with peers (Wehman et al. 2014).

Historical Background

Deficits in adaptive behaviors such as self-help skills have historically been included in definitions of mental retardation/intellectual disability and developmental disabilities. One of the earliest definitions to allude to deficits in self-help skills was Tredgold's (1937) definition of mental deficiency, which he defined as "a state of incomplete mental development of such a kind and degree that the individual is incapable of adapting himself to the normal environment of his fellows in such a way to maintain existence independently of supervision, control or external support" (p. 5).

The American Association on Intellectual and Developmental Disabilities (AAIDD) has included a criterion of adaptive deficits in each of the iterations of the definition of mental retardation it has published since 1961 (Beirne-Smith et al. 2006). Similarly, the definition of mental retardation/intellectual disability in the most recent edition of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* (American Psychiatric Association 2013) also includes the criterion of adaptive deficits related to self-help skills. Interestingly, the current DSM definition of autism spectrum disorder does not require deficits in adaptive behavior other than social skills for diagnosis.

Additionally, the legal definition of a developmental disability (which includes autism spectrum disorders), as defined by the Developmental Disabilities Assistance and Bill of Rights Act of 2000 (P.L. 106–402, pp. 7–8), does include deficits in self-help skills:

(A) In general, the term "developmental disability" means a severe, chronic disability of an individual that:

- (i) Is attributable to a mental or physical impairment or combination of mental and physical impairments
- (ii) Is manifested before the individual attains age 22

- (iii) Is likely to continue indefinitely
- (iv) Results in substantial functional limitations in three or more of the following areas of major life activity:
 - (I) Self-care, (II) receptive and expressive language, (III) learning, (IV) mobility, (V) self-direction, (VI) capacity for independent living, and (VII) economic self-sufficiency
- (v) Reflects the individual's need for a combination and sequence of special, interdisciplinary, or generic services, individualized supports, or other forms of assistance that are of lifelong or of extended duration and are individually planned and coordinated

Given the inclusion of adaptive deficits in the legal definition of developmental disabilities as noted above, there has recently been a push to closely examine the adaptive functioning of individuals on the autism spectrum who do not also meet criteria for an intellectual disability (i.e., those with average cognitive ability). Research has shown that even those individuals with ASDs who have average cognitive ability often exhibit significant deficits in adaptive behaviors including self-help. Thus, there has been a movement to consider adaptive functioning in addition to cognitive ability when determining services for individuals with ASDs (Chawarska and Volkmar 2005; Shea and Mesibov 2005).

Changes in federal law regarding special education have recently acknowledged the importance of self-help skills as a part of the more global functional skills repertoire. These functional skills are needed for persons with ASD to function as independently as possible in life. The reauthorization in 2004 of the Individuals with Disabilities Education Act (IDEA) included new requirements that a student's Individualized Education Program (IEP) targets both functional and academic skills. Functional goals are those outside the academic realm that include everyday routines in life. Because functional skill needs will vary from child to child, self-help skills may be addressed in an IEP, depending on the unique needs of the individual child (Howey 2008).

Current Knowledge

Challenges to Skill Acquisition

While the majority of children learn self-help skills such as bathing and dressing with ease, as noted above, many children with autism have great difficulty with this process and often require formal instruction in the area of self-help (Scheuermann and Webber 2002). Adults and adolescents with ASDs frequently exhibit significant deficits in self-help skills compared to their cognitive skills. For example, standardized scores for daily living skills on measures of adaptive behavior typically average anywhere from 15 to 30 points lower than IQ scores for individuals with ASDs who have average cognitive ability (Shea and Mesibov 2005). When compared to nondisabled children who have similar cognitive skills, children with autism spectrum disorders often have significantly lower scores on standardized measures of adaptive behavior (Chawarska and Volkmar 2005).

That children with ASDs have difficulty learning self-help skills is not surprising when the specific characteristics associated with autism are taken into account. Sensory issues can negatively impact learning self-help skills such as bathing or eating. Additionally, difficulties with sequencing and understanding social expectations may make learning self-help skills more difficult or less motivating (Shea and Mesibov 2005). Furthermore, Volkmar and Wiesner (2009) suggest that because children with autism tend to be more rigid and dependent upon specific contexts for learning, they have difficulty generalizing skills to new situations (e.g., bathing and dressing at home is a different skill than bathing and dressing at grandparent's house or in gym class). Thus, whereas a neurotypical child may only have to learn a skill once, a child with autism may have to learn the same skill many times in many different situations.

This challenge with needing step-by-step instruction can often be due to issues with praxis. Praxis is the ability one has to think of and plan new motor acts; it is also called motor planning. Functional praxis is based on adequate foundation skills in the areas of sensory processing,

neuromuscular control, and motor control (Cook 1991). Cognition also plays a part in one's ability to conceive, sequence, and perform a new motor skill (Tomchek 2001). Impairments in praxis are often noted in individuals with autism. Persons with autism may have motor planning issues related to motor skill but may also have other, less clearly understood factors contributing to praxis issues (Tomchek).

Another challenge in learning self-help skills that may relate specifically to children with autism spectrum disorders is the role of language and socialization. Anderson et al. (2007) state that typically developing children are often motivated to learn new self-help skills in order to gain approval from parents, peers, or others. Because many children with autism may not seek social reinforcement, they may be less motivated to practice and learn these skills. Additionally, while neurotypical children will often learn self-help skills naturally through observation, interaction, and caregiver modeling, this may be ineffective with a child who has an ASD. Rather, children with autism are more likely to require step-by-step formal instruction and tangible reinforcement in order to learn basic self-help skills. Furthermore, studies have shown that even when adolescents with autism know how to perform certain self-help skills, when left to function independently, they often simply *do not* do them, perhaps because many individuals with autism are not motivated by factors such as social acceptance (Shea and Mesibov 2005).

Commonly Used Assessment Tools

It is clear that from an early age, adaptive behavior, including self-help skills, is considered a critical area of development. In fact, Part C of the IDEA Amendments of 2004 mandates that states must provide services to children under age 3 who need early intervention services if they experience delay(s) in cognitive, physical, communication, social or emotional, or adaptive development. To this end, many curriculum-based and criterion-based measures include adaptive behavior/self-

help skills as one of the primary developmental domains assessed.

For both children and adults, self-help skills are routinely included in broader measures of adaptive or independent behavior. Four commonly used assessment measures are highlighted below:

- *Adaptive Behavior Assessment Scale-Third Edition (ABAS-3)*: The ABAS-3 provides a complete assessment of adaptive skills for persons from birth to 89 years. It covers the broad domains of conceptual, social, and practical and examines 11 specific skill areas, including self-care (feeding, personal hygiene, dressing). The ABAS-3 has five rating forms, each of which is designed for a specific age range and respondent. A General Adaptive Composite score is provided in addition to domain and skill area scores (Harrison and Oakland 2015).
- *Vineland Adaptive Behavior Scale-Third Edition (Vineland-3)*: The Vineland-3 is a measure of adaptive behavior in individuals from birth to 90 years. The Vineland-3 examines personal and social skills considered necessary for everyday living across three domains including communication, daily living skills, and socialization; it offers optional motor skills and maladaptive behavior domains as well. Within the daily living skills domain, specific focus is on personal care such as brushing teeth, feeding, toileting, dressing, and bathing. The Vineland-3 forms include the interview, parent/caregiver rating, and teacher rating; the measure provides an overall Adaptive Behavior Composite and domain scores (Sparrow et al. 2016).
- *Scales of Independent Behavior-Revised (SIB-R)*: The SIB-R is a comprehensive, norm-referenced tool that assesses 14 areas of adaptive behavior and 8 areas of maladaptive or problem behavior. One of the primary domains is personal living, which allows examination of eating, toileting, dressing, and self-care. The measure can be administered via interview or by checklist procedure and is appropriate for individuals from infancy through 80+ years. There are three versions of

the SIB-R available for use: full scale, short form, and early development form. The SIB-R provides a broad independence score as well as a cluster score for personal living (Bruininks et al. 1996).

- *Pediatric Evaluation of Disabilities Inventory* (PEDI): The PEDI is a clinical assessment tool used to assess the functional skills and performances of children from the ages of 6 months to 7.5 years old. It can also be used to determine the skills of children older than this age whose functional skills may be below those expected of a 7.5-year-old child with no disabilities. The PEDI measures abilities in three domains: self-care, mobility, and social function. Specific to self-care, the PEDI focuses on mealtime skills and utensil use, dressing, basic hygiene skills, and bowel and bladder management. The PEDI also includes a caregiver assistance scale, which provides information regarding the level of help a child needs to complete a domain-specific activity or skill. Information for the PEDI may be obtained via structured interviews, observations of the child, or professional judgment of therapists and/or teachers (Haley et al. 1992). This measure has been revised to be available as a computer adaptive test, the PEDI-CAT for use from birth through 20 years of age (Hayley and Coster 2010).

Teaching Self-Help Skills and the Use of Evidence-Based Interventions

Though children with autism spectrum disorders do not appear to learn and generalize the use of self-help skills as naturally as typically developing children, with formal instruction, many individuals with ASDs learn these skills quite well. In fact, self-help skills can be acquired relatively quickly with appropriate instruction because these skills often play to the strengths (and are less dependent on the weaknesses) of many children with autism. Specifically, learning self-help skills may involve concrete thinking, fixed sequential actions, and little necessary social interaction (Anderson et al. 2007).

As mentioned before, children with autism may have greater difficulty generalizing skills to different contexts and settings. Therefore, whenever possible, self-help skills should be taught in the same way and same environment as they will be performed. Furthermore, it is important to involve teachers, parents, and any additional caregivers in self-help skill training in order to ensure the child is taught the skill in the same way across contexts (Scheuermann and Webber 2002). Because any delay in the acquisition of self-help skills will most likely become more significant with age, it is important to begin teaching adaptive skills such as dressing and undressing, personal care, and toileting as early as preschool in order to promote independence in adolescence and adulthood (Volkmar and Wiesner 2009). Self-help skill acquisition may be “put off” as teaching self-help skills takes time and effort on the part of the teachers (this may often be the individual’s parents) and the learner. Resources are available to assist parents and other caregivers in teaching self-help skills; for example, Baker and Brightman (2004) provide strategies designed specifically to improve independence skills, including self-help, for children ages 3 to preadolescence. Sicile-Kira (2006) lists several strategies that help adolescents with autism to acquire basic self-help skills including the use of schedules, picture icons, task analysis, and video modeling.

Selected strategies that may be effective for teaching self-help skills are highlighted below; these intervention techniques have been effective for teaching a variety of skills to individuals with ASD (National Professional Development Center on Autism Spectrum Disorders 2011). Clearly, when selecting an evidence-based intervention, the choice should be determined by the need (s) and abilities of the individual and the target issues.

Behavioral Approaches

One method of teaching self-help skills that has had well-documented success is applied behavior analysis (ABA). The Board Certified Behavior

Analysts (BCBAs) work with caregivers to develop structured programs to teach children necessary skills using principles of behavior analysis and reinforcement (Anderson et al. 2007). ABA utilizes many behavioral techniques, such as discrete trials to teach self-help skills to children with autism. Discrete trials involve breaking complex tasks or concepts into simpler, more concrete tasks. In this method, the therapist may give the child a prompt or cue that signals what the child should do. When the child performs the desired response correctly, she/he is given a reward, which in ABA is referred to as a reinforcer (Volkmar and Wiesner 2009).

Another behavioral method of teaching self-help skills is called chaining. Chaining is similar to discrete trials in that it involves breaking a complex task into many basic tasks. The main difference between discrete trials and chaining is that in chaining, each small task serves as the prompt or signal to begin the next task and that each subsequent task serves as a reinforcer for the task that preceded it. There are two types of chaining: backward chaining and forward chaining. In backward chaining, the last task in the complex sequence is the first basic task that is taught; thus, teaching starts at the end and moves backward to the beginning of the complex task. First, the child is physically guided through all of the steps of the chain. The next time, physical guidance will be used until the last step of the chain. At that point, the parent or therapist will wait for the child to perform the task independently or with reduced prompting. When the child completes the task, reinforcement is given. Once the child has mastered the final task independently, she/he is ready to learn the second to last task in the chain. The next time through the chain, physical guidance will be stopped just before the second to last task. Then the child will independently complete the final two tasks. This continues until the child has mastered the entire chain independently. In forward chaining, the opposite occurs. Training begins with the first “mini-task,” and subsequent tasks are completed with physical guidance. Once the child masters the first task in the chain, she/he is then required to complete the first two tasks in the chain before

receiving physical guidance and so on until the entire chain is learned (Anderson et al. 2007).

Visual Supports

Progress can be further increased by using visual aids whenever possible in order to make the skills even less abstract (Kluth and Shouse 2009). Visual supports have a strong evidence base (Hume 2008) as practical, usable interventions for persons with ASD. Visual supports refer to objects, pictures, text, or a combination thereof provided to help a person understand and remember a concept or a task. Geis and Tomchek (2001) noted children with autism use their visual channels more effectively to process their world. Examples of visual supports include picture schedules, simple text checklists for routines, and charts combining words and symbols as behavioral reminders. Symbols for a dressing routine could include the following picture sequences for the daily routine (Fig. 1):

Sicile-Kara (2006) noted that picture icons were valuable in teaching routines to adolescents on the autism spectrum. Specific attention should be given to ensure that nonverbal teens know what the icons/symbols mean prior to their use in a dressing or self-care routine.

Social Narratives

Social narratives describe situations based on social and physical cues or teach specific social skills or behaviors. They can be individualized to meet the needs of the learner and may include pictures to assist the individual in gaining specific skills or responding appropriately (Collet-Klingenberg and Franzone 2008).

Perhaps the most widely known protocol, Carol Gray’s Social Story, is a comprehensive intervention used to explain a concept or skill to a person with autism using a specific format. A Social Story™ describes a situation, skill, or concept in terms of relevant social cues, perspectives, and common responses in a specifically defined style and format. The goal of a Social

Self-Help Skills, Fig. 1 Picture sequence of dressing routine. (Copyright © Do2Learn)

Story™ is to share accurate social information in a patient and reassuring manner that is easily understood by its audience; it is hoped that an individual's improved understanding of events and expectations may lead to more effective responses (the Gray Center, "What are Social Stories™?").

Video Modeling

Though it was noted above that children with ASDs often do not learn as readily from models as many typically developing children do, there are some types of modeling that are effective for teaching self-help skills to children with autism. One of these is video modeling (Charlop-Christy et al. 2000). Video modeling involves videotaping a model exhibiting a skill. The recording is then shown to the child with autism, who then learns to imitate the model. Children with autism are more likely to imitate actions they see in videos than those they see in person, perhaps because imitating live models has a greater social component. Additionally, the model in the video never alters his/her performance of the task as a live model will do, which can appeal to the child's preference for sameness. There is a particular type of video modeling that is gaining favor called video self-modeling. In video self-modeling, the child is

videotaped completing the task. The child can then watch the video and observe himself/herself completing the task; thus, the child serves as his/her own model. This technique is effective if the child is able to complete a task periodically, but is not consistent (Anderson et al. 2007). Additionally, it is theorized that by serving as his/her own model, the child may be more confident in his/her ability to correctly complete the task because the video serves as proof that she/he has been successful in it before (Buggey 2009).

Peer-Mediated Instruction and Intervention

Peer-mediated instruction and intervention (PMII) is an evidence-based practice that is best characterized by its use of competent peers to facilitate the learning and display of appropriate behaviors by the child with a less complex set of skills (Neitzel 2008). Peer-mediated strategies are built upon careful prompting and shaping of child behaviors by typical peers embedded in child-initiated interactions within natural contexts (Rogers 2000) and can be implemented with preschool-aged children as well as older students. PMII has been shown to have positive effects on academic, interpersonal, and personal-social

development (Maheady et al. 2001). Briefly, with PMII, once a particular skill is targeted as a need for the child with ASD, a skilled peer is selected and taught the necessary steps to model or teach the targeted skill with adult guidance and supervision. The peer then models the targeted skill in specific settings and situations.

Future Directions

Clearly, the acquisition of basic self-help skills should be viewed as a critical and necessary step in the overall development of individuals with autism spectrum disorders. An individual's ability to perform self-help skills has a strong influence on school, work, and social success. In addition, consideration of self-help skills, including more complex IADLs, may impact future decisions with respect to independent living arrangements as well as educational and vocational placements in adulthood. Thus, while it remains important to address an individual's needs in core areas of autism such as communication, behavior, and social skills, it is equally important to focus on developing self-help skills from a young age in order to allow children with ASDs to grow into independent adults with full lives.

Self-Injurious Behavior (SIB)

Jeffrey Danforth

Department of Psychology, Eastern Connecticut
State University, Willimantic, CT, USA

Definition

Self-injurious behavior (SIB) is behavior in which the individual inflicts injury on themselves. The range of potential self-injurious behavior is quite staggering and disconcerting. SIB may include head banging (the most common form) on walls, floors, or tables; finger, hand, or wrist biting; hair pulling; eye poking or gouging; hitting self; and scratching self. Many individuals display multiple types of SIB. SIB is “one of the most dangerous and debilitating behavior problems in the entire field of developmental disabilities” (Volkmar et al. 2009, p. 157).

SIB is a serious concern for caregivers of individuals with autism. The behavior may cause emotional reactions in families and service providers that are incompatible with reasoned practical intervention. Furthermore, SIB may lead to secondary health problems such as bruising, bleeding, infection, and head trauma that serve as setting events for more maladaptive behavior and in extreme cases may cause further neurological impairment. Compared with individuals with autism who do not exhibit SIB, individuals with autism who do exhibit SIB are more likely to be placed in residential treatment settings (Borthwick-Duffy et al. 1987).

SIB should not be confused with “non-suicidal self-injury” (NSSI), a syndrome recently proposed for inclusion in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association 2000). Whereas the purpose of neither syndrome of behaviors is resultant death, NSSI usually consists of repeated superficial self-injury with sharp objects done by typically developing adolescents between ages 15 and 19. SIB consists of the wide array of behaviors noted above done by individuals with developmental disabilities.

Current Knowledge

In the Diagnostic and Statistical Manual of Mental Disorders, SIB is not a defining feature of autism. It may not occur in an individual diagnosed with autism, and it is not limited to people with autism but may also present in individuals with mental retardation with or without a diagnosis of autism and in people with specific genetic disorders such as Lesch-Nyhan syndrome. Nonetheless, the prevalence of SIB in autism is much greater than in typically developing children (Dominick et al. 2007) and individuals with other developmental disabilities (Bodfish et al. 2000). SIB is more common in the severe and profound levels of mental retardation (Handen and Gilchrist 2006). Furthermore, the rate of SIB across individuals can range from thousands of times per day to once every few weeks. Generally, SIB seems to diminish as language development improves. Amelioration of SIB typically includes a variety of applied behavior analysis interventions and sometimes psychopharmacology.

Applied Behavior Analysis

The first step in applied behavior analysis is determination of variables controlling the behavior, a functional analysis. The controlling variables for SIB are as varied as the types of SIB, and there appears to be no causal relationship between a specific type of SIB and specific controlling variables. Many variables maintain problem behavior (Martin and Pear 2007), and these variables may develop, shape, or maintain SIB (Durand and Crimmins 1988; Minshawi 2008).

Functional Analysis

Some SIB is maintained by social positive reinforcement. For example, typical caregiver reactions might include attention in the form of hugging, getting close to the person, reprimands, or verbal attempts to sooth the person (Iwata et al. 1994). This is identified when functional analysis consistently shows that social attention follows behavior or when the person with autism smiles at, looks at, or approaches caregivers just behavior emitting SIB.

Some SIB is maintained by social negative reinforcement. In this scenario, antecedents to the SIB might be occasions where caregivers present demands that the person considers aversive. This may include instructions to complete a task or chore, say something or do schoolwork that is specifically difficult for the individual. Following this, the person may emit SIB that is reinforced (negative reinforcement) when the instruction or demand is withdrawn. Often, SIB is disruptive to the setting and results in such demands being withdrawn or postponed. SIB also causes some caregivers to stop making demands (Volkmar and Wiesner 2009). This is identified when functional analysis consistently shows SIB occurs when the person is presented with demands that are withdrawn following the SIB.

Some SIB is maintained by internal sensory positive reinforcement, sometimes referred to as automatic reinforcement. For example, SIB may lead to sensations or perceptions that include odd visual patterns, repetitive sounds, and tactile or kinesthetic sensations (Guess and Carr 1991). Some individuals with autism have sensory deficits that include high thresholds for pain, and there is speculation that some SIB is reinforced because it is experienced as pleasurable self-stimulation rather than aversive pain (Boucher 2009). This is identified when functional analysis consistently shows that SIB occurs when the individual with autism is alone, in the absence of external positive reinforcement or escape/avoidance conditions. Caregivers may report that the SIB is unrelated to any task or situation or that it occurs when there is a lack of external stimulation. The section on neurobiological research below briefly addresses such models for SIB.

Conversely, some SIB seems elicited by antecedent stimuli rather than maintained by reinforcing consequences. Although the sensory organs of individuals with autism are not compromised, some individuals with autism appear hypersensitive to stimulation (Dawson and Toth 2006). Sometimes this is referred to as sensory dysfunction that includes auditory, tactile, or visual defensiveness. Therefore, SIB may be

elicited by loud, high-pitched, or sudden noise (e.g., other children squealing, fire alarms, or loud music); certain textures of clothing or food; or lights that blink, shine directly in a person's face, or have high wattage. Such SIB may appear highly emotional in nature and is identified when functional analysis consistently shows that SIB occurs when specific stimuli or circumstances present or in settings paired with those stimuli. Conceptually, there are occasions when this is consistent with the logic of negative reinforcement described above. However, this is not social negative reinforcement but rather internal sensory negative reinforcement. For example, if playground noise at school recess elicits SIB by a child, it might be reasonable to assume that the noise is aversive to the child. Thus, when stimuli paired with going to playground are presented, such as after a specific class or walking down the hallway in line toward the playground, the child with autism may emit SIB that causes adults to disallow the "fun" playground opportunity, when in fact the SIB is negatively reinforced by escape/avoidance of the noisy playground.

Treatment

The second step in applied behavior analysis is manipulation of the variables that function to control the SIB and/or shaping desirable behavior that serves the same function, thereby decreasing the strength of SIB. The treatment is selected based on the functional assessment described above as well as the individual characteristics of the individual with autism, including IQ level. Typically, procedures are combined and highly individualized (Kahng et al. 2002; Volkmar et al. 2009).

If SIB is maintained by social positive reinforcement, then that reinforcement contingency is altered. One potential procedure is simply ignoring the person when they emit SIB, known as extinction. This is a deceptively complicated procedure because it is very difficult for caretakers, especially parents, to wholly ignore SIB. If caretakers occasionally give attention to SIB, whether or not it is intentional, then the SIB may become stronger because intermittent

reinforcement can be more powerful than continuous reinforcement. Iatrogenic effects may also include temporary increase in the rate of SIB at the outset of treatment (an extinction burst) and spontaneous recovery when the individual is not in the same setting where extinction was implemented. An alternative procedure allows caretakers to give attention to the person when they are not engaging in SIB, called differential reinforcement of zero responding (DRO). In this case, social attention is presented only if the SIB does not occur during a specified period. Typically, the length of time chosen is the average time interval between behavior occurrences. For example, if a child emits SIB four times per hour, the procedure is arranged to provide social attention every 15 min that the child does not emit SIB. Then, the schedule of reinforcement is thinned and social attention is presented every 20 min that the child does not emit SIB, and so forth. A disadvantage of extinction and DRO procedures is that they do not teach appropriate behavior, and sometimes the overall rate of reinforcement remains low if SIB continues. A third alternative is a procedure where caretakers give social attention for behavior that is incompatible with SIB, a response that cannot be emitted at the same time as SIB. This is differential reinforcement of incompatible behavior (DRI) or differential reinforcement of alternative behavior (DRA). For example, if functional analysis reveals that SIB is emitted when faced with challenging academic requirements, teachers may give social attention whenever the child requests help in that context. The hope is that as requests for help increase, SIB decreases.

If SIB is maintained by social negative reinforcement, once again the functional contingency between the behavior and consequence is altered. In some cases, caretakers simply insist, or persist, when presenting demands such that the SIB does not function to allow escape from demands. Sometimes, this procedure is impractical because the SIB compromises the individual's health. An alternative is similar to the DRI procedure described above. If a child exhibits SIB when demands are presented, shaping the child to sign

"no" and then withdrawing the demands contingent upon the signed "no" may reduce SIB because the function of "no" is identical to the function of SIB. The potential disadvantage is the remaining problem of a child who escapes demands. In some cases, cost-benefit analysis will reveal that the advantages of reduced SIB outweigh the disadvantages of escape from work. The DRI procedures described here are consistent with data illustrating the negative correlation between language development and SIB. Among individuals with autism, as functional communication improves in rate and quality, SIB decreases.

SIB maintained by internal sensory positive reinforcement can be challenging to manage because the functional relations between SIB and its consequences may be difficult to identify, particularly among individuals with communication deficits. Enriching the quality and intensity of surrounding environments may attenuate the function of SIB that is reinforced by auditory or visual outcomes. Blocking may disrupt the reinforcement relationship between SIB and tactile stimulation. For example, if functional analysis of a child's SIB determines that the reinforcer for scratching face is tactile stimulation in the absence of external positive reinforcement or escape/avoidance conditions, gloves on the child's hands may reduce scratching because it no longer functions to produce the tactile consequence.

If SIB is elicited by antecedent stimuli rather than maintained by reinforcing consequences, then structural changes in the environment may be warranted. Sometimes changes in the environments are practical and inexpensive. For example, if SIB is elicited by the sound of the old electric pencil sharpener, a cost-benefit analysis may reveal that the most parsimonious solution is a new sharpener with a less abrasive sound or moving the sharpener to a different location. Similar to functional communication training described above, SIB may be weakened by teaching the individual with autism an adaptive response such as signing, "I don't like that noise," and then eliminating the sound contingent upon that

communication. In this manner, the signed communication replaces the function of the SIB. Systematic desensitization incorporates gradual exposure to stimuli that elicit SIB. For example, if the hustle and bustle of the local mall elicits SIB, then numerous short trips to the mall, with incremental increases in the length of each visit, may help habituation to the mall.

Punishment

Sometimes, punishment is used when SIB is recalcitrant or severe, although there are disadvantages to punishment procedures. The presentation of punishing stimuli (positive punishment) contingent upon SIB has included water mists, visual screening, aversive tastes and odors, and electric shock. The removal of reinforcing stimuli (negative punishment) contingent upon SIB has included timeout and response cost (the removal of enjoyable items and tokens or opportunities to engage in preferred activities). One advantage of punishment is that it can be used even if functional analysis fails to determine the function of the SIB, particularly SIB maintained by internal sensory positive reinforcement. However, the disadvantages of punishment are well documented. Punishment does not teach appropriate behavior, so one form of SIB may be weakened only to be replaced by another form of SIB that serves the same function. Sometimes punishment elicits emotional responses (sad mood, fear, anger) that are incompatible with learning. Individuals who receive punishment may learn to avoid the people who administer the punishment and the settings where it is administered. Timeout may work for some children with autism, but timeout may be ineffective if the behavior of the individual with autism is negatively reinforced by escape from social interaction or positively reinforced by internal sensory events or the opportunity to engage in stereotypic behavior.

Neurobiological Research and Psychopharmacological Treatment

Neuroleptics have long been used for treatment of SIB, as well as aggression and stereotypical/repetitive behavior. Risperidone is the most commonly

used atypical antipsychotic that targets dopamine-blocking agents (Chavez and Chavez-Brown 2006). Potential side effects include fatigue/sedation, increased appetite, and corresponding weight gain and drooling. Recently, the efficacy of olanzapine indicates some improvement of SIB, but side effects such as dystonic reaction (distorted twisting/movement of part or all of the body) limits its usefulness in children (Handen and Gilchrist 2006).

Neurobiological models have evaluated the potential relevance of the endogenous opioid peptide hypothesis, which suggests that SIB results in increased levels of beta-endorphin levels. The outcome is elevated pain threshold and tolerance of, or reward by, pain. This is consistent with the suggestions that some SIB is maintained by internal sensory positive reinforcement wherein SIB is reinforced because it is experienced as pleasurable. Naltrexone is an opioid antagonist that may decrease SIB in some individuals (ElChaar et al. 2006). Potential side effects include drowsiness, decreased appetite, and aggression.

Some have suggested that SIB is really a manifestation of internal compulsive thoughts, consistent with obsessive-compulsive disorder (Boucher 2009). An outcome of this proposal is limited research indicating the efficacy of selective serotonin reuptake inhibitors (SSRIs) such as Zoloft and Prozac (Aman et al. 1999).

Definition

Self-management interventions are multi-component behavioral strategies that emphasize the monitoring and regulation of behaviors and reinforcements (rewards). The core elements of self-management interventions involve (a) self-observation of a targeted behavior, (b) self-recording, and (c) delivery of a reinforcer. The identified person in treatment (e.g., client, child, or adult) is given a central role in managing behavior change. The client is taught to observe or monitor (self-monitor) and track (self-record or self-manage) his or her own behaviors by using a recording method (tallying the occurrence of a target behavior on paper or with a counter device). When treatment goals are met, the client is expected to obtain a reward (reinforcement). An emphasis on systematically promoting the client to independently engage in these skills is an integral aspect of the intervention. Although behaviors are referenced as the outcome of change, self-management interventions have been examined and used for therapeutic changes in mood and cognitions. A review of the literature suggests they are potentially efficacious for increasing adaptive behaviors and reducing unwanted behaviors.

Historical Background

Self-management interventions have a long history as a set of therapeutic methods to promote

and maintain behavior change. Self-management interventions also have been referred to as self-monitoring (e.g., Kazdin 1974), self-control procedures (Nelson and Hayes 1981), or self-reinforcement systems (e.g., Mahoney 1970). These interventions have been used to target changes in behaviors (verbal and nonverbal) as well as emotions and cognitions. However, the argument in the field has been that internal, unobservable thoughts and emotions may be difficult to self-monitor due to challenges with substantiating the accuracy of internal processes. Therefore, overt, observable behaviors have been proposed to be more amenable to self-management interventions.

Most of the instrumental research and development in self-management interventions began in the late 1960s to early 1970s (Kazdin 1974; Mahoney 1970; cf. Korotitsch and Nelson-Gray 1999). The principles and methodology of self-management interventions developed from the field of behavioral psychology. It is strongly rooted in behavior modification principles and, later, cognitive-behavioral theories (Mahoney 1970). Since then, it has evolved and widely been adapted as a psychotherapeutic method for a range of clinical populations and conditions. Self-management interventions are often used in clinical settings and can be used alone as the primary therapeutic tool or integrated within a larger treatment package (e.g., Cognitive-Behavioral Therapy).

Self-management procedures are grounded on the notion that the client takes on the role of the “behavioral engineer” (Mahoney 1970). Historically, self-monitoring has been used for both assessment or information gathering and intervention purposes. Self-management for assessment purposes emphasizes the accuracy of a client’s self-monitoring to obtain and provide data on targeted behaviors (e.g., for diagnostic or treatment development purposes). In contrast, self-management interventions are often based on a triad of skills – self-monitoring, self-recording, and self-reinforcement (or for some pediatric populations, parent- or teacher-delivered reinforcement) – for the explicit purposes of behavioral change. The emphasis is on discerning the

expression of target behaviors rather than accuracy of self-recording. Much of the early work on self-management interventions included not only clinical applications but component analyses of the various variables involved in self-management interventions (cf. Kazdin 1974; Mahoney 1974). Since then, more of the contemporary research on self-management interventions with people with autism spectrum disorder (ASD) involves direct clinical application (e.g., Lee et al. 2007).

Rationale or Underlying Theory

Mechanisms for Behavioral Change. Self-management interventions have been hypothesized to emphasize the active role of the client in promoting and maintaining change. The client’s role in directing change is pivotal and is an integral mechanism in this intervention (Mahoney 1972). Clients determine whether behaviors will be increased or decreased to obtain a desired outcome (reward). As a result, emphasis is placed on self-management procedures to be gradually transitioned from therapist management of contingencies to the client (Mahoney 1970). Particular emphasis is placed on the client to learn to discriminate when the target behaviors occurred to obtain the reward. By doing so, the client develops self-awareness through contingency management skills (i.e., the notion that reward is only obtained contingent upon the expression of target behaviors). Some clients with poor impulse control can learn this association even if parents and teachers remain in control of the reinforcement.

Initiating Behavioral Change. At the very foundation of self-management intervention principles is the notion that self-monitoring achieves significant changes in behaviors, referred to as the “reactivity effect” (Kazdin 1974; Korotitsch and Nelson-Gray 1999). The premise is that self-monitoring alone leads to reactive behavioral effects and is a widely accepted aspect of self-management interventions. The client’s enhanced self-awareness of behavioral expression is proposed to be pivotal to initiating behavioral

change. Kanfer (1970) asserted that self-regulation is achieved by the active process of the client's own observations, evaluations, and obtainment of rewards. Awareness of one's own behaviors is proposed to promote the acquisition of adaptive behaviors. Self-awareness helps people recognize and appreciate new contingency relationships within their environment to develop adaptive behaviors (Mischel 1973).

Maintenance and Generalization of Behavior Change. These instrumental concepts underlying self-management have led to subsequent hypotheses that self-management interventions facilitate clients to independently manage their symptoms while decreasing their reliance on the administration of intervention by clinicians (Harrower and Dunlap 2001; Koegel et al. 1992). Self-management procedures are considered to be economical and easy to transport, making it relatively easy to use the intervention across a variety of settings. These factors have been hypothesized to promote generalization of behavioral change in ASD (Koegel et al. 1992). Also, it has been speculated to increase self-regulation of symptoms and has been referred to as a pivotal area that can elicit change in a variety of other symptom domains related to ASD (Koegel et al. 2001). The emphasis on increased client self-sufficiency in managing the treatment of symptoms seems to be especially pertinent in using this intervention for children with ASD and their families.

Goals and Objectives

The primary goal of self-management interventions is the development, maintenance, and generalization of adaptive behavioral change. The goal is to facilitate an awareness of the interaction between one's behavior and the surrounding environment, including contingency management of rewards (Mahoney 1970). In the treatment of ASD, generalization of desired changes across contexts that extend beyond the treatment setting is also an aim (Koegel et al. 1992). Another goal is to increase independence of symptom management by children (and families of children) or adults.

Treatment Participants

Self-management intervention research has been conducted with a wide range of ages and for a variety of presenting issues in both typically and atypically developing populations. The youngest age group in which this intervention has been targeted in ASD has been with preschool children (Newman et al. 2000); however, it has been applied more frequently with school-aged children (Lee et al. 2007). Children as young as 3 years of age appear to accurately self-monitor behaviors with brief training provided by a clinician. The intervention has been used and appears to be effective across children and adolescents with varying ASD diagnoses (i.e., autism, Asperger's disorder, and pervasive developmental disorder-not otherwise specified), functioning levels, and for treating a range of social, communication, and behavioral impairments (Apple et al. 2005; Pierce and Schreibman 1994; Wilkinson 2005). Some targeted behaviors have included independence skills such as completing daily living tasks (e.g., schedules), school performance, social skills, conversation skills, play skills, and managing challenging behaviors such as disruptive and repetitive behaviors. For example, in youngsters with ASD, self-management intervention was used to successfully increase behavioral variability in the play-related behaviors of three young children (preschool to 6 years of age) diagnosed with autism and mild cognitive impairments (Newman et al. 2000). In another study, school-aged children with ASD (ages 7, 12, and 13 years) demonstrated an increase in independent, appropriate (i.e., functional) toy play and a decrease in self-stimulatory behaviors that maintained in unsupervised and new play settings with the implementation of self-management intervention (Stahmer and Schreibman 1992). Youngsters with ASD (ages 5 and 6) demonstrated appropriate school performance behaviors in their classrooms and decreased off-task behaviors (e.g., running out of the classroom; Koegel et al. 1999). Self-management intervention as part of a video modeling treatment package effectively increased initiations of compliment giving in three young children with ASD (ages 4–5) in

comparison to video self-modeling alone (Apple et al. 2005). Children with ASD (ages 6 and 11) demonstrated increased appropriate verbal responses and decreased disruptive behaviors and social-communicative responses across clinical, home, and community settings with self-management intervention (Koegel et al. 1992).

In contrast, there are only a few research studies examining self-management interventions in adults with ASD. In one study, nine young adults diagnosed with high-functioning ASD (IQ above 80) between the ages of 17–25 years demonstrated a significant improvement in appropriate, self-initiated question-asking skills with the implementation of a self-management treatment package (Palmen et al. 2008). Further research in the application and efficacy of self-management interventions across the age span is necessary.

Treatment Procedures

Self-management interventions often involve the following fundamental treatment elements: (a) identifying and explicitly defining goals for behavioral change (to promote self-monitoring), (b) developing skills for the client to monitor and record the occurrence or nonoccurrence of identified behaviors (self-recording), and (c) facilitating the client to obtain rewards once the targeted behaviors have been demonstrated (self-reward). There exists variability in the implementation of self-management interventions, but most incorporate the basic elements presented above to some degree. For example, Newman et al. (2000) used all three elements of self-management intervention by having the children self-monitor their play behaviors with the experimenters, “record” when they displayed flexible play by taking tokens from a jar, and then trading in these tokens to obtain a reward. In another study, children viewed appropriate social initiations on a video and then learned to monitor and self-record initiations in the classroom setting with their peers by placing a check mark in a box that was printed on laminated paper for one child or pressing a button on a wrist counter for the other children (Apple et al. 2005). The children selected their reward before

beginning the self-management session for the day and approached their teachers once they had accumulated the designated number of points. Traditionally, self-management interventions are provided in an individual therapy setting that involves the client and the clinician across a range of settings such as the clinic or naturalistic environments within the community (e.g., Koegel et al. 1999). There is some preliminary evidence that it can also be implemented in a group treatment setting (e.g., Palmen et al. 2008).

More specific procedures for self-management among youth involve (1) identifying a range of child-preferred rewards and allowing children to designate items they would like to earn; (2) presenting them with a clear, individualized description of the targeted behavior using child-friendly language; (3) informing children of the number of “points” (target behaviors) necessary to obtain the reward; (4) teaching them to use self-management recording materials and track points through modeling and role playing (i.e., Self-Monitoring Training); (5) presenting children with opportunities to engage in targeted behaviors; (6) prompting them to mark a point once the target behavior was demonstrated; and (7) immediately presenting them with the selected reward once the agreed-upon number of points are achieved. Self-monitoring training (i.e., discrimination training) is often provided within self-management interventions. This involves a clinician teaching the client to be aware of behaviors by distinguishing desired targeted behaviors from undesired behaviors. Both types of behaviors are usually modeled by the clinician, and the client is asked whether such behaviors would warrant a point on the self-management sheet. The length of time providing the training appears to vary based on functioning levels and complexity of targeted behaviors. Training can be brief and has been accomplished in a 1-h period provided twice a week (e.g., Stahmer and Schreibman 1992).

Promoting independence with self-management skills is an overarching goal of this intervention method. In combination with the basic therapeutic elements, most interventions emphasize gradually facilitating the individual to develop autonomy with the intervention. Clinicians incrementally

decrease their involvement in implementing the intervention as clients demonstrate reasonable success with both self-management skills and treatment goals. One primary method has been for clinicians to gradually fade prompts provided to the client. These prompts, which can be verbal (e.g., reminders to mark the occurrence of a target behavior immediately after it occurred) or nonverbal (e.g., physically helping the child track responses by placing a tally mark on a sheet of paper), eventually transition from direct (e.g., a verbal reminder to check off a point each time the target behavior occurred) to indirect prompts (e.g., a brief reminder provided once at the beginning of the session for the client to as many “points” as possible). The frequency of prompts provided by the clinician and the degree of involvement in implementing the intervention are eventually tapered off. In one study, children were initially coached in using wrist counters to track their points (or responses) and reminded to press the counter each time the children asked an appropriate question. Gradually, such reminders and assistance were decreased as the children demonstrated success with using the self-management tools and asking appropriate questions during conversations (Koegel et al. 1992). Also, the frequency or duration of the target behavior necessary to obtain a reward is gradually increased. The rationale behind this process is to incrementally increase the targeted behavior in a manageable way to promote feelings of success in the client, maintain rapport, and preserve treatment motivation. In addition, the process involves extending the length of time before self-reinforcement occurs in order to promote maintenance of targeted behaviors in a naturalistic manner. Stahmer and Schreibman (1992) initially had children receive a point for demonstrating appropriate play behaviors for 30 s, which incrementally increased to 20 min in order to obtain a point. Koegel et al. (1992) initially rewarded children for obtaining 1 point for asking an appropriate question at the beginning of treatment. Eventually, children needed to obtain 30 points to obtain the reward.

There is preliminary evidence that recording and tracking one’s *own* behaviors results in increased behavior change in comparison to

being provided with *external* prompts that targeted behaviors have occurred. A study by Newman and Ten Eyck (2005) demonstrated that children’s social initiations increased dramatically when they kept track of their initiations by taking a penny out of a bowl compared to a condition in which the children with ASD were externally provided with a penny by adults for initiating social behaviors. In fact, it seems that complex social behaviors in children with ASD such as social-communicative initiations are significantly improved using self-management intervention (e.g., Apple et al. 2005) in comparison to other methods such as video self-modeling. There is strong evidence that recording accuracy does not seem to be crucial for treatment effects to occur (Lee et al. 2007). Children may occasionally forget to self-record after engaging in the targeted behaviors. Some researchers have remarked that this phenomenon may be indicative of the targeted behaviors becoming integrated into the children’s natural behavioral repertoire (Koegel et al. 1992; Newman et al. 2000). Conversely, there did not seem to be significant instances of children purposefully recording behaviors when they did not occur in order to obtain a reward. Therefore, the expectation for self-recording seems to be that clients should demonstrate reasonable accuracy during treatment.

The identification and use of highly motivating rewards is an integral aspect of this treatment. In the literature, these have included access to highly desired snacks or drinks, toys, activities (e.g., playing video games), or small prizes such as stickers. Rewards are conducted through some form of a preference assessment. This process involves the clinician identifying child-preferred items or activities by conducting a direct observation or gathering input from caregivers or from the children themselves. For example, in one study, children were provided with a prize bag that contained a range of child-preferred prizes (e.g., stickers, figurines, small toys; Apple et al. 2005). Highly motivating rewards can be reserved for self-management intervention in order to ensure reinforcing properties. Reinforcement immediately following the self-management intervention appears to be successful particularly when self-

management skills are just developing. Most studies of youngsters with ASD used contingent rewards immediately following a self-management session (e.g., Apple et al. 2005; Koegel et al. 1999). In one study of an adult with mild cognitive impairment, delayed reinforcement by accumulating a certain number of points to exchange for motivating items at the end of the week was effective, but somewhat less powerful in initially maintaining complex behaviors (e.g., Moore 2009).

Materials used to monitor behaviors consist of visual cues such as checklists with questions related to the occurrence of the target behavior (e.g., Did I stay in my seat?) or check boxes printed on paper for children to mark the occurrence of the desired behavior. Materials to record points consist of writing instruments such as pens, markers, or crayons (e.g., Stahmer and Schreibman 1992). Other materials to designate points included stickers or tokens (e.g., Newman et al. 2000). Devices such as timers or wrist watch counters have been used in an attempt to provide more discrete self-monitoring and decrease the need for clinician-delivered prompts. For example, a young adult with ASD used a digital watch to keep track of the time intervals (e.g., 5 min) in which he engaged in appropriate on-task behaviors when completing classroom assignments (Moore 2009). After the watch beeped when 5 min had passed, he marked whether he demonstrated on-task behaviors during that time interval by placing tally marks on a sheet of paper. In many studies, wrist counters have been used for children to track their targeted behaviors (e.g., Koegel et al. 1999). Overall, self-management materials appear to be manageable and successfully used across ages and functioning levels and can be tailored to meet the unique needs of each person while still maintaining treatment efficacy.

Several variables contributing to enhanced treatment effects have been identified. Treatment effects were enhanced when motivation for change within the client was high (Lipinski et al. 1975); immediate self-recording after each target behavior occurred rather than after a long delay (Mahoney et al. 1973); clients were aware of explicit performance standards/goals and

provided with feedback (Kazdin 1974); and positive self-reinforcement by obtaining a reward for engaging in the targeted behavior rather than retracting rewards for the absence of behaviors was used (e.g., giving oneself a punitive consequence by removing access to preferred items as used in a cost-response strategy; Humphrey et al. 1978). Additionally, younger children may need more guidance and explicit rehearsal of behaviors, facilitation procuring and obtaining rewards, and support from adults or other support people to learn and successfully use self-management procedures (Lee et al. 2007). A combination of the above variables appears to have greater effects than self-monitoring alone or another single component of self-management intervention by itself (Kazdin 1974).

Efficacy Information

Much of the literature on self-management interventions in ASD has been conducted using single-case research design. Single-case research models use rigorous and systematic methodology to closely examine behaviors when specific variables are manipulated (e.g., implementation of treatment) with a small number of participants (more scientifically rigorous studies include at least three participants). At this time, no large group design studies exist examining this intervention in ASD. Positive treatment effects of self-management interventions have been long established as either the sole treatment intervention or within the context of other treatment methods across studies. Lee et al. (2007) conducted a meta-analysis on 11 single-case studies to examine the effectiveness of self-management interventions among preschool and school-aged children with ASD. They concluded that, overall, self-management interventions are effective in promoting and maintaining positive behaviors. The average effect size was approximately 82% based on single-case design meta-analysis using percentage of nonoverlapping data (PND). PND is one type of meta-analyses to measure the effect size to synthesize single-case research. Higher PND scores reflect greater

treatment efficacy with scores ranging from 0% to 100%. Efficacy criteria range from ineffective (scores below 50%), questionable (50–70%), effective (70–90%), to highly effective treatments (90% or greater). The percentage of data points in the treatment phase that do not overlap with the highest value of data in the baseline phase (pretreatment) is calculated. Treatments employing self-management strategies were effective regardless of age group (preschool children vs. school-aged children), emphasis on specific self-management components (self-monitoring vs. self-reward components), or self-management materials (paper sheet vs. tokens). A trend for increased efficacy was observed in programs that were individualized for the children, coparticipants (e.g., adults or peers) provided support in monitoring the children's target behaviors, and self-management was conducted in natural settings (e.g., the home). Most studies also demonstrated maintenance effects (behavioral gains maintained even with the removal of self-management procedures) and generalization effects (behavioral gains demonstrated in novel settings or activities). For example, Stahmer and Schreibman (1992) demonstrated that prior to treatment, the three children with ASD in their study engaged in approximately less than 40% of appropriate toy play during each session. With intervention, all three children increased the percentage in which they demonstrated appropriate play to an average of 88% for child 1, 80% for child 2, and 96% for child 3. Generalization effects were evident in a novel setting once self-management procedures were faded. Two of the three children demonstrated appropriate play at levels similar to that during treatment after a 1-month follow-up (greater than 80% of appropriate play each session). In another study, two children with ASD demonstrated appropriate schoolwork performance during baseline (prior to treatment) approximately for 55% across sessions (Koegel et al. 1999). During intervention, levels of performance increased to approximately 95% for both children and maintained at this high level even after clinician involvement had been completely removed.

Outcome Measurement

Outcome measurements vary across studies and depend on the treatment targets. In general, given that many of the self-management treatment studies in ASD are based on single-case research design paradigms, outcome variables tend to be based on observable behaviors that have been recorded using frequency- (event recording) or interval- (duration) based variables gathered through direct observation or videotaped recordings. Frequency data refer to measuring the number of times behaviors occurred during a designated period of time. Interval recording systems measure the total number of intervals during which the targeted (e.g., 10-s interval) behaviors occurred within a specified overall time period (e.g., 10 min). Data are based on either the entire session or representative timed samples or data probes (e.g., last 10 min of a session). The manner in which this data is calculated varies and has consisted of frequency counts, rates, or percentages. Behaviors are carefully and specifically operationalized to accurately capture changes over time. Reliability data are typically reported in the literature to ensure that raters (typically at least two raters for a specified portion of the data) were both accurate and reliable in measuring behaviors. In one study, outcome measures consisted of the percentage of play opportunities in which children demonstrated appropriate, varied play (Newman et al. 2000). Children with ASD were presented with ten opportunities to play during each session. Each instance of varied play was totaled for the session and divided by the total number of opportunities presented and then multiplied by 100 in order to obtain a total percentage of opportunities the children engaged in varied play per session. Koegel et al. (1992) examined the frequency of appropriate and inappropriate verbal responses using an event recording system. The total number of these responses was summed for each data probe. The presence of disruptive behaviors was measured using an interval recording system. Each instance of disruptive behavior that was present during a 30-sec interval (from a 15-min data probe) was calculated and then divided by the total number of intervals to

obtain the percentage of 30-sec intervals in which disruptive behaviors were observed during each session. Additionally, a few self-management intervention studies also measured the occurrence of targeted behaviors in typically developing children to serve as a marker for the expected frequency or percentage of behaviors expected (e.g., Koegel et al. 1999).

Qualifications of Treatment Providers

Self-management interventions with the ASD population are typically provided by trained professionals with advanced degrees in psychology or education and training in evidence-based practices with the ASD population. Also trained professionals provide ongoing supervision and training in self-management interventions to support staff (e.g., school aides or teachers), parents, or behavioral clinicians without advanced degrees in order to provide treatments that can be maintained by various people in the child or adult's life.

Self-Other Distinction and Social Cognition in ASD

Marcel Brass and Jan R. Wiersema
Ghent University, Ghent, Belgium

Definition

Autism spectrum disorder (ASD) is characterized by marked impairments in social interactions. One of the most basic elements constituting the ability to interact with other social agents is to form representations of the self and the other while also being able to distinguish these representations. How crucial the ability for self-other distinction is for social interactions becomes obvious in the motor domain. Recent theories have emphasized that perceiving the actions of other agents activates corresponding motor representations in the observer, by means of the mirror neuron system (MNS; Gallese and Goldman 1998). When we see somebody else acting, this activates a motor representation similar to the one that is active when planning and executing the action oneself. Such a common representational basis of observed and executed actions makes it necessary, however, to distinguish these representations. Without self-other distinction, externally triggered motor representations would lead to overt imitative behavior. Interestingly, such an imitative response tendency can be observed in specific social situations (the so-called chameleon effect, Chartrand and Bargh

1999) and in specific pathologies (Lhermitte et al. 1986; Brass et al. 2003).

In the context of ASD, the so-called “broken mirror hypothesis” has been proposed (Williams et al. 2001). This hypothesis suggests that ASD is characterized by an impairment of the mirror system, which leads to a deficit of mirroring other people’s behavior. However, this theory has been strongly contested. Automatic imitation (not requiring higher level cognitive processes) has been found to be intact or even enhanced in ASD (Sowden et al. 2016; Spengler et al. 2010), while electroencephalography (EEG) and functional magnetic resonance (fMRI) studies on MNS functioning have yielded rather inconsistent findings, with less, typical, or more MNS activity in ASD (e.g., Martineau et al. 2010; Raymaekers et al. 2009). Current approaches of shared representation of perception and action rather postulate an abnormality in modulating MNS activity in the process of self-other distinction. Importantly, self-other distinction is also required in other social-cognitive processes. Our ability to take different spatial perspectives requires that we can distinguish our own perspective from the perspective of someone else (Samson et al. 2010). Furthermore, theory of mind (ToM), the ability to attribute mental states (beliefs, intentions, desires) to oneself and others, and to understand that others have mental states that may differ from one’s own also requires self-other distinction. In situations where other people hold beliefs that differ from our own beliefs, we need to distinguish between self- and other-related beliefs. Indeed, many researchers in the domain of social neuroscience have argued that self-other distinction is a low-level neurocognitive mechanism that lies at the basis of many domains of social functioning (Brass et al. 2009; de Guzman et al. 2016; Sowden and Shah 2014; Uddin 2011). At the neural level, research has indicated the crucial involvement of the temporoparietal junction (TPJ) in self-other distinction (e.g., Spengler et al. 2009). The TPJ is a brain region at the intersection of the inferior parietal and the superior temporal cortex. While the specific functional role of the TPJ and its functional neuroanatomy is still controversial (Krall et al. 2014), there is ample evidence that

the TPJ plays a crucial role in social cognition. Interestingly, the TPJ is also one of the core brain areas of the so-called ToM network and studies have consistently implicated TPJ dysfunction in ASD during ToM and other socio-cognitive tasks (e.g., Lombardo et al. 2011; Nijhof et al. 2018; Spengler et al. 2010). Together these findings led to recent theories of ASD pointing to a potential deficit in self-other distinction that might underlie social cognitive impairments in ASD, associated with TPJ dysfunction (e.g., de Guzman et al. 2016; Lombardo et al. 2011; Spengler et al. 2010).

Historical Background

Already in the earliest writings on autism the problem of distinguishing self from other was recognized. In his seminal article, Kanner wrote: “She used to talk using ‘you’ for herself and ‘I’ for her mother or me, as if she were saying things as we would in talking to her.” (Kanner 1943, p. 228). In this entry, Kanner described 11 children, who seemed to be unable to relate to other people, were self-absorbed, and who showed a general lack of interest in other people. Kanner noticed that none of the eight children that could speak used personal pronouns properly; they referred to other people by using first person pronouns (e.g., calling their mother “I”) and contrariwise used pronouns referring to others, to refer to themselves (when wanting a candy, saying “You want candy”). While this peculiar use of pronouns might index self-other distinction difficulties, Kanner did not refer to it as such but explained it in terms of echolalia. In his theoretical work, Hobson (1990) argued that self- and other-awareness is essential for the comprehension and hence proper use of pronouns, and hypothesized that ASD involves a specific impairment in understanding “I” in relation to “Thou,” which may lead to echolalia as well as other ASD-related behavior. More recently, researchers have started to systematically investigate potential deficits in neurocognitive mechanisms of self-other distinction in ASD (Lombardo et al. 2011; Spengler et al. 2010).

Current Knowledge

In the motor domain, self-other distinction has been investigated with the imitation-inhibition task (Brass et al. 2000). In this task, participants have to carry out a movement in response to an imperative stimulus (e.g., a number) while observing congruent or incongruent finger movements. In incongruent trials, participants have to suppress the automatic tendency to imitate the movement in order to carry out the instructed movement. Based on the idea, that movement observation leads to an automatic activation of a corresponding motor representation in the observer, it has been argued that suppressing the observed movement in incongruent trials requires self-other distinction and activates the anterior medial prefrontal cortex (aFMC) and the TPJ (Brass et al. 2005). Furthermore, it has been shown that brain activation in the imitation-inhibition task overlaps with brain activation in a ToM task and in an agency task, supporting the idea of a common underlying mechanism of self-other distinction that is linked to the TPJ (Spengler et al. 2009). More recent neurostimulation studies have shown a causal role of the TPJ in self-other distinction (Bardi et al. 2017; Santiesteban et al. 2012; Sowden and Catmur 2015).

It is commonly known that individuals with ASD have difficulties representing others and the idea of altered self-representation is also rather old (Frith and Happe 1999; Kanner 1943). While earlier theoretical work has claimed that ASD may involve impairment in understanding “I” in relation to “Thou” (Hobson 1990), only recently a specific deficit in neurocognitive mechanisms of self-other distinction has been proposed for ASD (Lombardo et al. 2011; Spengler et al. 2010). The idea that self-other distinction is compromised in the motor domain is supported by clinical observations. Young children with ASD often show pronoun reversal, echopraxia, and echolalia (involuntary imitation of motor and speech respectively) (Kanner 1943; Uddin 2011), and studies have shown decreased ability to inhibit imitative motor actions in ASD (Spengler et al. 2010) (see, however, Sowden et al. 2016 for

failures to show this relationship). In addition, there is neuroimaging evidence for this claim. In a sample of high-functioning adults with ASD, it was demonstrated that self-other distinction in the imitation-inhibition task was related to reduced brain activation in the TPJ and the anterior medial frontal cortex (aMFC) in a ToM task, supporting the idea that self-other distinction might be compromised in ASD (Spengler et al. 2010). Atypical empathic behavioral and physiological responses in ASD have also recently been linked to self-other distinction (De Coster et al. 2018). Furthermore, a recent electroencephalography (EEG) study demonstrated that self-other distinction in a task where participants had to match observed behavior and tactile stimuli was compromised in ASD (Deschrijver et al. 2017). Here, participants observed a hand touching a surface, combined with a tap-like tactile sensation at their own hand that either matched or mismatched the tactile consequence of the observed movement. Neurotypicals showed modulation of the P3 component for incongruent trials, which was absent in the ASD group. Crucially, this effect reliably correlated with self-reported social and sensory difficulties in ASD. Taken together, there is evidence from different domains that problems in self-other distinction might play an important role in ASD. Such problems might also result in compensatory strategies leading to the avoidance of social stimuli more generally. If people with ASD have problems to distinguish self from other when interacting with other social agents, they might prevent such problems by avoiding social interactions.

Future Directions

While there is augmenting evidence that self-other distinction is impaired in ASD, further research is needed to determine how such a deficit relates to the various social and nonsocial problems in ASD. As argued above, Theory of Mind requires self-other distinction, hence ToM problems can be partly explained by self-other distinction deficits. The observation that people with ASD avoid

social interactions could be explained as a compensatory strategy as outlined above. However, the link between compromised self-other distinction and nonsocial difficulties, such as restricted repetitive behavior and atypical sensory processing is less well understood, and warrants further investigation. Future research also has to clarify the link between self-other distinction problems and atypical processing of self-related stimuli. There is increasing evidence of altered self-referential processing in ASD, incorporating mental aspects of self, such as autobiographical memory difficulties and atypical neural responding to hearing one's own name (Nijhof et al. 2018), but also physical aspects like own face processing (Uddin 2011). As briefly outlined above, an integral part of defining oneself is by distinguishing oneself from others. Hence, if self-other distinction is impaired, self-referential processing might be compromised as well. Although coming from separate research lines, ToM deficits and altered processing of self-related stimuli in ASD may be tightly linked as a disturbed mechanism of self-other distinction may underlie both domains of impairment.

At a more general level, it needs to be addressed how problems with self-other distinction relate to recent attempts to explain ASD within a predictive coding framework. The predictive coding framework states that the brain constantly makes predictions about the world and processes incoming sensory information in light of those predictions (priors). ASD has been argued to be associated with inflexible precision in regulating sensory expectations based on these priors (Goris et al. 2018; Van de Cruys et al. 2014). It is not yet known how this relates to altered representations of self and other in ASD. The concept of self-agency which lies at the heart of self-other distinction is however strongly linked to predictive processes. Hence, self-other distinction problems might be a special case of a general predictive coding deficit. Finally, a better understanding of the role of self-other distinction and the TPJ in ASD may provide important putative targets for future interventions, such as neurostimulation of the TPJ and training of self-

other distinction, to improve social-cognitive functioning in individuals with ASD. Further research is needed, however, to address the question how other parts of the ToM network such as the aFMC are related to self-other distinction problems.

Self-Recognition

Emily Kilroy

Mayes Lab, Yale Child Study Center, New Haven, CT, USA

Definition

Self-recognition refers to recognizing the “self” as separate from others. The term self encompasses various modalities (e.g., physical, emotional, psychological) which are unique and representative of an individual. Generally, attributes of self are categorized as either physical or psychological. Physical aspects of the self (e.g., face) typically refer to material embodiments of the self and awareness of personal agency, whereas psychological characteristics include multiple cognitive constructs such as personality traits and subjective perspectives (Gillihan and Farah 2005). The ability to self-recognize can be used as an index of self-awareness as well as an early developmental marker. A face is among the

earliest and the most common embodied representations of one's self. Self-face recognition occurs between 18 and 24 months and is considered crucial for the development of a self-concept and successful social behavior as it signals the emergence of sophisticated levels of self-awareness. The differentiation of self and others progresses continuously over the first 24 months, culminating in a clear identification of self-image and self-awareness (Lewis 1991). Impaired or inhibited emergence of self-recognition is linked with developmentally delayed disorders such as Autism Spectrum Disorder (ASD).

Historical Background

Self is foundational to the term Autism. The word Autism is derived from the Greek word “autos” meaning “self.” Leo Kanner first applied this term to children demonstrating complete self-focus and who were seemingly indifferent to social interaction (1943). Researchers have since considered individuals with Autism to have an “absent self” or reduced self-awareness in order to explain the observed impairments (Blakemore and Frith 2003).

Early research on visual self-recognition suggests children with ASD do not have impaired bodily self-recognition and are capable of acknowledging their own reflection (Dawson and McKissick 1984). Self-recognition is classically examined through a mirror paradigm originally developed by Gallup (1970) to investigate self-concept in nonhuman primates. Variations of this paradigm have been used to empirically study self-recognition in infants and children. The protocol involves secretly marking an infant's nose and observing their response upon placing the infant in front of a mirror. A response directed at the mark infers self-recognition. At approximately 2 years of age, young children are able to recognize themselves and exhibit a definite recognition of their reflection by touching their noses. Children with ASD have shown variable ability in this task compared to typically developing children (TD) (Dawson et al. 1984).

However, impaired ability in this task is not considered to be a deficit of the disorder since it has not been found to be related to ASD characteristics. Dawson and McKissick (1984) demonstrated that language, motor, and social deficits were not related to self-face recognition. Moreover, some studies that report significant self-recognition impairments in children with ASD also found that their sample exhibited mental ages below their chronological age. Therefore, variable or absence of self-recognition in the mirror task can be thought to be a reflection of a developmental delay and not a specific inability characteristic of ASD (Dawson and McKissick 1984; Ferrari and Matthews 1983). This suggests self-focused observations in ASD may be related to other “self” domains such as more abstract or cognitive representations of self.

A reduced sense of self in children with ASD is evident in cognitive aspects of self such as self-awareness and self-referencing. For example, while observations of embarrassment and coyness during the mirror task usually appear around 2 years of age in TD children (Amsterdam and Greenberg 1977), similar self-conscious reactions were reported missing in children in ASD who performed the same task. These findings are congruent with research reporting a reduction in the use of self-referencing pronouns in ASD children. Concurrent with the ability to recognize one’s self in a mirror is the onset of personal pronoun use (e.g., “I” and “me”; Preyer 1889). The use of personal pronouns in children with ASD has been shown to be reduced and is thought to be indicative of a failure to self-reference (Fay 1979). A lack of self-awareness reactions and use of personal pronouns points to an underdeveloped or impaired cognitive sense of self in ASD. Such impairments early in development are thought to be related to an increased difficulty distinguishing between self and other and subsequently increased social impairments (Kanner 1943). More recent research has focused on how the ability to distinguish between self and others differs in children with Autism.

Current Knowledge

The multidimensional nature of self-recognition lends itself to be examined from both a behavioral and neurological perspective. While some aspects of self-awareness are atypical in ASD, others appear to be intact. Abstract representations of self, such as identifying personal feelings and conceptual ideals, are more affected than awareness of one’s physical self. The formation of a secure and balanced self-representation is important to social understanding (Decety and Sommerville 2003). Researchers have investigated self-recognition in ASD at various stages of development at both the behavioral and neural level.

Behavioral

Studies implementing various self-referencing paradigms have reported aberrant self-recognition ability in children with ASD from a young age. A reduction in the use of self-reference has been well characterized. Studies examining verbal expressions of self have found that individuals with ASD have specific difficulties identifying personal experiences, mental states, and emotions (see Capps et al. 1995; Frith and Happé 1999). Retrospective studies on individuals with ASD and their siblings demonstrated a reduction in self-reference, such as name orientation, based on the examination of first birthday home videos. Longitudinal behavioral studies following infant siblings at high risk for ASD (i.e., siblings of children with ASD) have found orienting to one’s name in the videos was a behavioral marker that differentiated between those children who were later diagnosed with ASD and those who did not. The authors suggest these early observations are a sign of reduced social motivation and are unrelated to developmental delays alone (Zwaigenbaum et al. 2005). This attenuated tendency to self-reference is seen throughout development and into adulthood. In a study looking at self-reference and memory performance, adults with ASD did not perform as well during the memory task condition that involved words

presented in a self-related manner (i.e., “Does the word describe you?”) compared to the control group (Toichi et al. 2002). Additional longitudinal studies are needed to track participants throughout development.

Expanding upon the mirror task, a revised digital version of the paradigm uses previously recorded video to examine self-recognition. This delayed self-recognition (DSR) task tests whether children recognize their past self as opposed to their present self in a modified version of Gallup’s mirror paradigm. A sticker is placed on a child’s head in secret and is later shown a video of the sticker being placed on their head. The majority of children with ASD showed no difficulty realizing that a sticker was actually on their head nor did they significantly differ in prompts to acknowledge the sticker. The DSR task demonstrates children with ASD have no impairment recognizing between their current and past self (Lind and Bowler 2009). This finding is also congruent with research on self-recognition of agency in ASD. Agency refers to the person causing or generating an action. In an action-monitoring task, Williams and colleagues (2008) showed that children with ASD performed similarly to typically developing individuals by showing stronger self-reference when following and recalling their own actions compared to the actions of the experimenter. Both the DSR and agency monitoring studies suggest bodily self-recognition is unimpaired in ASD.

While physical attributes of self-recognition are intact in ASD, it is unclear if the neural bases of these processes are being employed the same way as in TD individuals. For example, individuals with ASD may employ alternative cognitive mechanisms, such as matching representations of like images to achieve the same results. Another caveat in many self-recognition studies is testing age. Due to the relatively older age at diagnosis, it is difficult to compare early developmental constructs in children with ASD that occur in the first few years of life. As of yet, no known self-recognition research has been reported on infants at high risk for Autism. Numerous neuroimaging studies, however, have examined the neural mechanisms in children and adults.

Neuroimaging

While specific brain region involvement may vary depending on different self-referential processes, the right prefrontal cortex plays a large role in self-recognition (Lou et al. 2004; Keenan et al. 2000). Self-face recognition research implicated the right hemisphere with various psychological aspects of the self (i.e., trait attributes, judgment of self, self-reflection) (Platek et al. 2006; Uddin et al. 2005). While it appears that self-referencing, particularly self-face recognition, is lateralized in the right hemisphere (RH), the left hemisphere (LH) is likely to play an important role. Several functional Magnetic Resonance Imaging (fMRI) studies have shown bilateral activation during different operationalizations of self (Kircher et al. 2000). Research on split-brain patients (where the corpus callosum is severed and communication between the two hemispheres has been lost) also report discrepant findings in regards to hemispheric differences when examining self-processing (Keenan et al. 2003). The relatively few self-face studies in ASD provide some evidence to suggest that self-face recognition tasks elicit activity in similar cortical regions as neurotypical individuals. However, the patterns of activity within these regions differ.

Neuroimaging research on self-recognition in ASD has largely focused on neural processes distinguishing between self- and other-faces. Self-face recognition paradigms typically included morphed versions of a participant’s face with that of a familiar or unfamiliar other’s face to varying degrees. Participants are asked to identify at what point the stimulus looks more like themselves than the other person’s face (Uddin et al. 2006). Several imaging techniques using a similar paradigm have supported RH specialization for self-face recognition in control participants (Keenan et al. 2000) and altered RH patterns of activity in individuals with ASD (Gunji et al. 2009). In particular, the right inferior frontal gyrus (IFG) appears to be involved in self and other face distinction and to show reduced activity in individuals with ASD. The right IFG is part of the Mirror Neuron System (MNS) and is thought to contribute to successful understanding of

other's intentions as well as self-recognition (Uddin et al. 2005). More specifically, in an fMRI study by Uddin et al. (2008) children with ASD exhibited different activation patterns in the right IFG, compared to the TD group. TD children exhibited almost equal activation to self and other face processing, while ASD only exhibited significant activation when viewing their own faces (Uddin et al. 2008). The authors suggest that this dissociation may point to a neural substrate for self-focused and decreased other focused social motivation. They also propose that the shared representation for self and others seen in TD children may be a neural mechanism by which we understand others and reduction of activity in the IFG during other-face processing may indicate reduced social understating in children with ASD. Kita et al. (2010) likewise reported right IFG activation in a self-recognition near-infrared spectroscopy study. Control and ASD participants exhibited higher levels of oxygenated hemoglobin in the right compared to left IFG when viewing self-face stimuli. They also reported that an increase in IFG activation was inversely related to ASD symptom severity, such that lower activity was related increased ASD symptom severity (Kita et al. 2010).

Neuroimaging studies have also found individuals with ASD have difficulties during cognitive self-referential tasks such as mentalizing. High-level inference-based mentalizing involves cognitive representations of self and other and recruits similar neural systems in regards to physical self and other representation. In an fMRI study by Lombardo (2010) TD and ASD participants made reflective judgments about themselves and a nonclose other (i.e., president). Neurotypical adults more strongly recruited the ventral medial prefrontal cortex (vMPFC) when mentalizing about themselves. In contrast, the ASD group activated the vMPFC equally when mentalizing about self and other. Further, the magnitude of self and other distinction in the vMPFC was negatively correlated with social impairments in the ASD participants. This study suggests that specific dysfunctions in cortical midline structures of the brain, such as MPFC, may alter patterns of

activity when mentalizing (Lombardo et al. 2007). Uddin et al. (2008) found the reverse dissociation during a face recognition task, suggesting that differences between neurotypical and ASD differ depending on the nature of the self-referential process.

Other studies have also reported a dissociation between self and other perception in individuals with pervasive developmental disorder (PDD) (i.e., ASD). In an electrophysiological study (Gunji et al. 2009), atypical patterns of self- and other-recognition were demonstrated in children with PDD compared with TD children and adults. The TD groups made a distinction between self and familiar stimuli, but the children with PDD did not (Gunji et al. 2009).

The dual nature of self, simultaneously being similar and different from other individuals is central to the development of social cognition (Lombardo and Baron Cohen 2010). Neural activation related to distinguishing between self and other appear to be atypical in ASD, suggesting that altered self- and other-recognition may be linked to deficits in social cognition in the disorder.

Future Directions

Self-recognition research in Autism has primarily focused on specific self-representation processes. Neuroimaging in particular have used task-related MRI to examine self-recognition mechanisms and networks. Future research should explore the basic mechanisms and the levels at which different domains of self (i.e., physical and psychological) relate to one another. The relationship between patterns and levels of activation that involve the MNS and higher mentalizing systems should also be explored in the same sample. Presently, there are few longitudinal studies, more are needed to examine developmental changes in self-referencing and recognition. It would also be interesting to investigate different cultural perspectives of self and how interdependent or independent views of self modulate self-recognition mechanisms.

In order to discuss self-recognition in children with autism spectrum disorder (ASD), we will first need to embed the interest in self-recognition into a more general theory of the development of the self-system, in particular that aspect of the system referred to as the self-reflecting aspect of the self. Having done so, the measurement of this aspect of the system will be presented along with data on its development and the relation to brain function. Following this, the research on the development of self-referential behaviors in children with ASD and its relationship to brain function will be discussed (portions of this manuscript have appeared in *The Rise of Consciousness and the Development of Emotional Life* (©2014 Michael Lewis, Published by The Guilford Press)).

The Self-System

The terms *self* and *nonself* in reference to plants and to cells, as well as to humans, are used. If the term self is confusing, consider several examples from the human literature. The term self-regulation is used when talking about newborn infants (Kopp 1982) and intersubjectivity in 6-month-olds (Rochat 2009; Stern 1985). Things do not get much better when we consider adult

humans, for example, the Western view of self as “I self” versus an Eastern view of self as “we self” (see Geertz 1984). Even dissociative identity disorder, the idea of multiple selves rather than a single self, has been identified (Ross 1989).

Even in everyday lives, people are confronted with explaining selves. Much of their motor action, although initially planned, is carried out by core processes of the body that include, by definition, self-regulation and self-other differentiation. The same, of course, is true of thinking. One level of self is necessary to formulate, at least sometimes, what it is that is wished to be thinking about, but another level of self does not appear to be involved in the processes that actually conduct the task of thinking. Consider this example: a person is given the problem of adding a 7 to the sum of 7s that precede it (e.g., $7 + 7 = 14 + 7 = 21 + 7 = 28$, etc.). It is clear that as subjects carry out this task, they cannot reflect on themselves doing the arithmetic. One aspect of the self has set up the problem, another solves it. These diverse examples from plants, cells, human newborns, and adults all address the topic of what it is that people mean when they use the term self.

It is important to remember that:

- All living systems self-regulate; in any living system, there needs to be communication between parts of that system. This can include a unit as small as a cell, a plant, or an animal or even a more complex organism. Self-regulation is a property of living matter. Self-regulation makes no assumptions about a mental state or self-awareness (McClelland et al. 2014).
- Some minimal differentiation between self and other is a necessary condition for action. How this differentiation is produced is unknown (see Butterworth 1992). What appears to be so is that all organisms, even such things as T cells, cannot act without at some level being able to distinguish between self and other. The ability to self-regulate or to distinguish self from other is part of the core processes of all living systems (von Bertalanffy 1967). It is not an extended consciousness as some believe (Damasio 1999).

- Even higher order functions such as perception, thinking, and complex actions, such as driving a car, can be performed by adult humans without a mental state or self-reflection; that is, without their being able to reflect on, look at, and observe the processes that allow these behaviors to be carried out.
- A unique aspect of some self-systems is self-reflection. By self-reflection we mean the capacity of a self to know it knows or to remember it remembers. It is this “meta” ability that is referred to as self-reflection. This reflective capacity of self-awareness may be uniquely human, although we may need to include the great apes who may be also capable of this.

Given the existence of the various levels of self, the question posed is: When I say “I know X,” is it the case that I *must* know that I know X? If it is the case that I can know that I know X, when is it the case that I do know that I know X? These kinds of epistemological questions require different levels of self. These epistemological questions are best addressed by the analysis of different levels of the self-system since from an epistemological point of view, knowledge can be bodily or reflective knowledge, but the knowledge of the knowledge is always a reflective self. Knowledge of the knowledge is the capacity of the self to reflect on itself. This ability to reflect on itself is what makes it so important to understand in the study of autism.

The Measurement of Self-Reflection

Measurement follows from the constructs that are made. If there is interest in the development of self, then the measurement of self-referential behavior is necessary. Because early imitation, intersensory integration, and coordination between infant and mother all are likely to reflect the core processes of self, they are not adequate measures of self-reflection.

The study of self-reflection in adults requires symbolic language capacity. In an adult, or typically developing child, it can be asked, “Who are

you?” “Tell me something about yourself,” or “Tell me something that you know that others don’t know.” Alternatively, following R. D. Laing (1970), we can see whether the child understands statements such as “I know, you know that I know where you put your teddy bear.” As is readily understood, all of these questions imply some idea the child has about itself, or its self-reflection, because the recursive knowledge about what others know about what you know explicitly implies a self referent.

Without language, however, the child with ASD cannot through language explain this idea to us. One alternative is to require, without using language, that children do certain tasks and see whether they can do them. If the child understands the task given, it is possible to demonstrate that the child has the idea, even though she/he does not have language. Thus, for example, in the work on deception (Allen and Lewis in preparation; Lewis et al. 1989) and in the research on theories of mind, Wellman (1990) and Moses and Chandler (1992), for example, have been able to show that the child can deceive and also place itself in the role of another. In each of these types of studies, there is an implicit theory of mind that includes self-reflection (see Carpendale and Lewis 2010; Chandler and Birch 2010).

Unfortunately, even these studies require that children understand complex language although they do not have to produce it or only need some early emerging capacities. A language measure, a bit less suspect, is that of personal pronoun usage. Because parents rarely use the label “me” or “mine” when referring to the child or to themselves (they say, “I am {or Mommy is} going to the store.”), the use of these terms by the child is likely to be a reasonable measure of self-reflection. This appears even more the case when children’s use of the terms and how they behave when using them are observed. In a typically developing child, it can be observed that as the child says “mine,” it also pulls the object away from another child and toward itself. Because moving the object toward oneself does not move the object as far away from the other as possible, the placement of the object next to the body, together with the use of the term “me” or

“mine,” appears to reference self-reflection. Typically developing children begin to use personal pronouns including “me” and “mine” by the latter part of the second year of life, which can provide a linguistic demonstration of the emerging mental state (Harter 1983; Hobson 1990).

Another procedure that can be used to measure self-reflection is self-recognition. Lewis has studied self-recognition in infants and young children in detail (Lewis 1992, 2003a; Lewis and Brooks-Gunn 1979a; Lewis and Ramsay 2004). The procedure is simple. Unknown to the child, their nose is marked with rouge and then the child is placed in front of a mirror, where it is possible to observe whether the child, looking in the mirror, touches its marked nose or whether it touches the image in the mirror. The data from a variety of studies indicate that typically developing infants even as young as 2 months, when placed in front of mirrors, show interest and respond to the mirror image. Children will smile, coo, and try to attract the attention of the child in the mirror, although they do not behave as if they recognize that it is they in the mirror; this is an evolutionarily derived adapted action pattern produced in the context of *babyiness*. Indeed, even dogs, cats, and older children and adults are attracted by babyishness. At older ages, when locomotion appears, on occasion, infants have been observed going behind the mirror to see whether they can find the child in the mirror. In addition, they often strike the mirror as if they are trying to touch the other. Somewhere around 15–18 months of age, they appear to begin to know that the images are themselves because they touch their noses or comment about their noses when looking in the mirror. Self-reflection is captured by the children’s use of self-directed referential behaviors. The touching of their noses when they look in the mirror seems to reveal that they know that it is “me” there.

The ability to use the mirror to reference herself has been mistaken for the child’s understanding of the property of mirrors. There is ample evidence that although children are able to produce self-referential behavior through the use of the mirror-mark technique, they do not know many of the properties of reflected surfaces; for example, they cannot use the mirror to find an

object only seen in its surface (Butterworth 1992). What is important about the self-referential behaviors in the mirror is that they need not be a marker of general knowledge about reflected surfaces but rather a marker for the child’s knowledge about itself. They are the equivalent of the phrase “that’s me.” This recognition, if put into words, says, “That is me over there; this is me here.”

Measuring other aspects of self-reflection is possible, pretend play in particular. From a variety of theoretical perspectives (Huttenlocher and Higgins 1978; Leslie 1987; McCune-Nicolich 1981; Piaget 1962/1951), it is apparent that pretense is an early manifestation of the ability to understand mental states including one’s own and others’. Pretense involves double knowledge or dual representation of the literal and pretend situation. The dissociable relation between the two allows the child to distinguish between appearance and reality. Research by Piaget (1962/1951) and subsequent investigators (Fein 1975; Lowe 1975; McCune 1995; Nicolich 1977) indicates that pretense emerges in children by the middle to latter part of the second year of life. The capacity for pretense not only marks self-reflection but also the beginning of a theory of mind that is based on mentalism, not that which is based on evolutionarily derived adapted action patterns such as gaze behavior, joint attention, social referencing, and preverbal communication abilities (Bretherton 1991; Carpenter et al. 1999; Leslie 1987).

There are studies that have examined the relation between verbal measures of self-recognition (including the use of the personal pronoun “me” and one’s name) and the mark-directed behavior (Bertenthal and Fischer 1978; Lewis and Ramsay 2004; Pipp et al. 1987). These studies have generally found that verbal measures appear after the mark-directed behavior (Harter 1983). It also is apparent that self-referential and pretense behaviors emerge at approximately the same point in development (see Lewis and Ramsay 2004). A mental state of self-reflection is taken for granted in Leslie’s (1987) model on the relation between pretend play and theory of mind. That pretend play emerges as soon as the onset of self-

recognition would support the belief that both reflect the emergence of self-referential behavior, as well as a source for a theory of mind.

In a series of studies on self-referential behavior, Lewis and his colleagues have established that self-recognition starts to emerge by 15 months and that, for the most part, all typically developing children demonstrate it by 24 months, thus showing an onset as well as offset (Lewis and Brooks-Gunn 1979b). Moreover, children with Down syndrome need a mental age of 15–18 months in order to show mirror recognition (Cicchetti and Sroufe 1978). Children who show self-recognition show self-conscious emotions such as embarrassment, while those who do not show recognition do not show embarrassment (Lewis et al. 1989).

Self-recognition, personal pronoun use, and pretend play all indicate self-referential behavior. It is apparent that, with development, self-representation increasingly becomes a more complex and multifaceted phenomenon that progressively includes other cognitive and evaluative aspects of self-knowledge (Lewis 2014). These results suggest that in terms of emergent time, self-recognition is earliest in the formation of a complex self-reflection. Of the three self-referential abilities assessed, self-recognition in mirrors was the one most likely to emerge first in development, suggesting that physical self-referential action may provide the core aspect of self-representation that continues to develop beyond the second year of life.

Consistent with the present findings is work that indicates children's emerging understanding of a theory of mind by the middle of the second year of life. For example, Meltzoff (1995) reports that 18-month-old toddlers have the ability to understand the intentions of others. After observing adult models demonstrate the intention to act in a certain way by starting, but not completing, a given activity, the toddlers, when given the opportunity, performed the complete acts the adult intended. Similarly, Asendorpf and colleagues (Asendorpf and Baudonniere 1993; Asendorpf et al. 1996) found increases in imitative play linked to the presence of self-recognition in 20-month-old infants. Indeed, many studies link

self-recognition to other abilities that mark more broadly the emergence of self-representation. For example, self-recognition is related to children's self-conscious emotions, empathy (Bischof-Kohler 1994), as well as altruism (Zahn-Waxler et al. 1992). Self-recognition is related to autobiographical memories (Harley and Reese 1999) and is associated with imitation (Asendorpf 2002). The degree of correspondence between self-recognition, pretend play, language self-referents, and the emergence of ownership suggests, in the typically developing child, the emergence of self-reflection in the middle of the second year of life (Friedman 2011). The absence or delay of self-recognition, pretend play with others, and personal pronoun usage during this time frame has been associated with mental age delays and with ASD, and this will be considered in more detail, but first we will discuss the role of brain maturation in self-referential behavior.

Self-Reflection and the Development of Brain Function

While social coaction between the child and its social world may affect self-reflection abilities, it is likely it does so through its effect on the development of brain functioning. Lewis and colleagues have used self-recognition in mirrors, personal pronoun usage, and pretend play as measures of self-referential behavior and have used these measures to examine the relation between brain function development and self-reflection.

Given that there appears to be a developmental onset, for typically developing children, of these self-referential behaviors usually absent before 15 months, given that a mental age of 15–18 months is necessary for its display, and given that it is absent or delayed in children with autism, it is likely that developing biological processes play an important role in the development of them. Finally, given that monkeys cannot, but the great apes and humans can, suggests a phylogenetic as well as an ontogenetic pattern. These findings provide strong support for the idea that brain development may be associated with the onset of self-reflection. But to be clear, brain

development itself is not a split-off feature of an encapsulated brain; the brain develops according to processes of probabilistic epigenesis, through complex relational bidirectional coactions with other bodily processes and environmental contexts (Overton 2006).

This idea of the significance of brain development for self-reflection is further supported by the findings that specific brain region activation is associated with adult self-referential behaviors. The left superior temporal gyrus and the left medial frontal gyrus are activated when subjects engage in a theory-of-mind task relative to reading sentences (Fletcher et al. 1995; Gallagher et al. 2000; Mitchell et al. 2002). Activation of the left superior temporal cortex (Brodmann area 22), the left inferior parietal cortex, and the left and right occipital cortices (BA 18) occurs when subjects judge whether adjectives are relevant to themselves (Fossati et al. 2003; Macrae et al. 2004). In a study of brain activation to hearing one's own name, Carmody and Lewis (2006) found activation in the middle and superior temporal cortex and the left middle frontal cortex. In general, there is agreement that self-referential behaviors activate regions near the temporoparietal junction, although there are data suggesting activation of the medial frontal cortex as well (Fletcher et al. 1995; Kampe et al. 2003).

To measure brain activation developmentally as a function of the capacity to show self-reflection, one would need to study the relation between the emergence of this representational ability and changes in brain function. Obtaining functional magnetic resonance imaging (fMRI) or positron emission tomography (PET) scans in very young children has been shown to be difficult (Souweidane et al. 1999), and there are few, if any, published fMRI studies of children between 15 and 30 months of age, which is the critical age range for the development of self-referential behaviors (Paus 2005; Saxe et al. 2004).

One way to study brain development is to use magnetic resonance imaging (MRI) to measure the relative amounts of gray and white matter in different cortical brain regions (Toga et al. 2006). MR images show a gray-white matter contrast in

a sequence that reflects the time course of brain development (Barkovich 2000, 2005; Paus et al. 2001), and changes in MRI features are informative in determining the developmental changes in white and gray matter for normal and clinical cases (Barkovich 2002). Different MRI techniques are available to assess brain development and involve either qualitative judgments or quantitative measures. Although the qualitative descriptions help characterize brain development, computational analysis of MR images allows the detection of individual changes in white matter that signal the biological underpinnings of development of motor, sensory, cognitive, and perhaps social changes. To that end, quantitative measures may prove more valuable than the qualitative judgments of change.

Quantitative measures include volumetric analyses of gray and white matter (Thompson et al. 2007), development of white matter relative to gray matter (Carmody et al. 2004), and the more recent diffusion tensor imaging (DTI) techniques to assess white matter integrity (Anjari et al. 2007). DTI provides data on the anatomy and the density of white matter fibers and development (Dubois et al. 2006), as well as providing images of the cortical association tracts (Mori et al. 2002).

Lewis and Carmody were interested in using the standard clinical MRI scans to assess brain development in both clinical and nonclinical groups. Quantitative scores based on the difference between white matter and gray matter were obtained using quantitative assessments of T2-weighted MR images for specific brain regions, which generate age changes in white matter development (Barkovich 2002; Dietrich et al. 1988; McArdle et al. 1987). Given this technique, it is possible to measure individual differences in development by region and relate these individual regional differences in development to individual differences in children's self-representation.

To study this problem, Lewis and Carmody (2008) studied 15 infants from 15 to 30 months of age and related their development of particular brain regions to their scores on a self-referential

scale made up of mirror self-recognition, personal pronouns, and pretend play. The findings from this study indicate that the degree of brain development in a specific region, independent of age, is related to the emergence of children's self-representation. This held for the self-referential score, as well as the three components that make up the score. It is the degree of development in the left temporoparietal junction that is most related to self-representational behavior. This is consistent with other findings that implicate the temporoparietal junction in its role in self-representational behavior (Samson et al. 2004; Saxe et al. 2004; Saxe and Kanwisher 2003). This brain region, as well as regions located nearby, has been found to be activated during several types of self-representational behaviors, such as when subjects engage in a theory-of-mind task relative to reading sentences (Fletcher et al. 1995; Gallagher et al. 2000; Mitchell et al. 2002), when subjects judge whether adjectives are relevant to themselves (Fossati et al. 2003; Macrae et al. 2004), and when subjects hear their own name (Carmody and Lewis 2006).

However, it should be noted that studies have found evidence for both left- and right-hemisphere involvement in self-representation; the left hemisphere shows greater activation on tasks involving self-representation, whereas the right hemisphere shows activation in tasks involving self in comparison with others. For example, Ruby and Decety (2001), using PET, reported left parietal activation when subjects mentally simulated an action with a first-person perspective and right parietal activation when subjects simulated an action with a third-person perspective (i.e., imagining the action of the other). In addition, Turk et al. (2002) found in a study of face recognition in a split-brain patient that the left hemisphere in comparison with the right hemisphere showed more activation to self than to a familiar face, whereas the right hemisphere showed more activation to familiar faces of others than to the self.

This work on typically developing children has important implications when we study children with ASD, a topic discussed next.

Self-Reflection and Self-Referential Behavior in Children with ASD

This section will first examine the abilities of children with ASD to show self-referential behavior. Following this, the examination of brain differences in children with ASD and self-referential behavior will be considered.

Self-Referential Abilities in Children with ASD

The developmental markers of self-referential behavior are delayed or absent in children with ASD. Looking at self-referential behavior found in 2-year-old typically developing children, Lewis and Ramsay (2004) showed that mirror recognition, personal pronoun use, and other-directed pretend play were related and occurring at approximately the same time. Children who recognized themselves in mirrors also showed personal pronoun use and engaged in complex pretend play that involved themselves and another. The data on typically developing children show that between 15 and 24 months they come to recognize themselves in mirrors (Lewis and Brooks-Gunn 1979b; Lewis and Ramsay 2004) and that personal pronoun usage also develops in the second year (Howe et al. 2003; Pipp et al. 1987).

Regardless of age, children with ASD show deficits in personal pronoun use and in other-directed pretend play. Personal pronouns are not used or are used inappropriately by children with autistic disorder (Lee et al. 1994). For example, children diagnosed with autism with an average mental age of 5–6 years were compared on production of personal pronouns to a group of language-delayed children matched in mental age to the autistic group (Loveland and Landry 1986). The children with autism had more difficulties producing correct personal pronouns than the language-delayed group indicating that children with autism are different from typically developing children by more than mental age deficiency differences.

Children with autistic disorder tend to engage in self-directed play rather than play involving others (Charman and Baron-Cohen 1997; Sigman 1998). Although children with autistic disorder

have the capacity to copy symbolic play, to perform self-directed symbolic play, and to imitate pretend play when prompted, these children produce fewer novel and unprompted pretend play acts relative to typically developing children (Rutherford and Rogers 2003).

In a study, Carmody and Lewis (2012) compared self-referential behaviors of a group of children with ASD who were 4 years of age with a group of typically developing children of 2 years of age. By 24 months, 100 % of the typically developing children showed self-recognition in mirrors compared to only 55 % of the 4-year-old children with ASD. Eighty-three percent of the typically developing 2-year-olds had personal pronoun usage, while only 60 % of the 4-year-olds with ASD did. Finally, while 80 % of the typically developing 2-year-olds showed pretense, only 35 % of the 4-year-olds with ASD showed pretense. Thus, these data are consistent with other studies which indicate that in children with ASD, self-referential behavior is either delayed or absent in comparison to typically developing children. It does emerge for some children with ASD at 4–6 years. However, there are a sizable number of children with ASD who are more severely affected who do not show these self-referential behaviors at all.

Several reports have suggested that mental age is the determining factor in the emergence of self-recognition and that once the mental age of 2 years is achieved, children with ASD will have self-recognition (Dawson and McKissick 1984; Ferrari and Matthews 1983; Spiker and Ricks 1984). The belief that mental age is the major factor in the inability of children with ASD to show self-recognition is still widely held. For example, Lind and Bowler in 2009 stated that for the mirror recognition task that "...a number of studies (Dawson and McKissick 1984; Ferrari and Matthews 1983; Neuman and Hill 1978; Spiker and Ricks 1984) have demonstrated that children with ASD are capable of mirror self-recognition at a mental age of 18 months (p. 643)."

That this capacity emerges later has been used to suggest that the lack of self-referential behavior in children with ASD is a function of mental age. For example, Dawson and McKissick (1984),

using the mirror recognition task, make such an argument. However, mental age alone cannot account for the failure to recognize oneself in the mirror. For example, Ferrari and Matthews (1983) found that the mirror self-recognizers having ASD had on average a mental age of 38 months, while non-recognizers had an average mental age of 22 months. Given repeated demonstrations that show that 80 % of typically developing children with a mental age of 21 months show self-recognition, the failure of the children with ASD to show self-recognition with an average mental age of 22 months does not support the idea that mental age alone accounts for the failure of children with ASD to show self-recognition. Given that social skills in children with ASD are more than two standard deviations below those predicted by their mental age and that deficits in social skills in children with ASD have been reported as early as 12 months (Bryson et al. 2007; Volkmar et al. 1993; Zwaigenbaum et al. 2005), it may be the case that mental age is not central to the failure of children with ASD in developing self-referential behavior.

In order to look at this question, Carmody and Lewis (2012) looked at the mental age of those 4-year-old children with ASD who passed and failed the three self-referential tasks – mirror recognition, personal pronouns, and pretense. For the latter two, there were no mental age differences, while only mirror recognition showed a mental age effect. Even so, the mental ages of the children with ASD who failed the mirror recognition task had mental ages well above 24 months (in fact, 35 months). Given these findings, mental age alone cannot account for these differences.

The nature of the origins of self-representational behavior remains to be determined. Many have argued for experiential factors in this development for typically developing children, arguing that social interactions give rise to self-referential behavior, and as a result of impoverished experiences of the child in relation to other, children with ASD fail to develop (Cooley 1902; Duval and Wicklund 1972; Hobson et al. 2006; Keller et al. 2004). Another view is that the emergence of self-representational behavior in typically developing children is a

brain maturational event (Leslie 2002; Lewis 2003b). Self-representation appears to emerge within an age window across many cultures (Keller et al. 2004; Priel and de Schonen 1986; Vyt 2001). In typically developing children, there is no mirror recognition before 15 months, but by 24 months all children exhibit it. Lewis and Carmody (2008) have shown that self-representation is related to the maturation of left temporoparietal junction (TPJ) in typically developing children. It is likely, therefore, that the cause of the deficits in self-representation in ASD is multiply determined. While both views of the origins of deficits in children with autism have compelling features, it is likely the case that brain dysfunctions affect both parent–child interactions and self-referential behavior in some epigenetic way to produce the defects we see in the 2–5-year period.

Brain Function Differences Between Typically Developing Children and Children with ASD

There has been considerable study of brain differences in typically developing children and children with ASD. There is too extensive a literature to include, and therefore only some general comments on brain size and function as they relate to self-referential behavior will be discussed here.

Brain imaging studies of children with autism have revealed the atypical growth patterns of the brain relative to typically developing children. For example, by two or three years of age, autistic boys have brain volumes larger than normal average in the cerebrum and cerebellum. This early excessive growth fails to be sustained as their pace of growth falls significantly below normal development in middle childhood (Amaral et al. 2008; Bauman and Kemper 2005). Not only are these overall differences indicative of different brains in the children with autism relative to those with typical development but specific brain region differences also have been found. There is some evidence that the frontal lobes are different in children with autism. It should be noted that Lewis and Carmody (2008) found that the temporal lobes and some frontal regions are associated with self-referential ability in typical development (see also Samson et al. 2004; Saxe et al. 2004).

Studying brain region development in children with ASD, Carmody and Lewis used similar MRI procedures as in earlier studies (Carmody et al. 2007; Carmody and Lewis 2006, 2010). In the 2010 paper, they looked at myelination differences by region, those including the medial frontal cortex, the temporal parietal junction, and temporal poles. Data based on typically developing children served as a reference for age-expected values of maturation for each region, and the results showed that for both the left and right medial frontal cortex, children with ASD showed significantly greater maturation than the typically developing children. However, the left temporal parietal junction of the children with ASD showed significantly less maturation relative to the typically developing group; the right temporal parietal junction showed no group differences. These data support their contention that children with ASD show specific brain region maturation differences relative to the non-ASD children such that the children with ASD show maturation in the frontal region which is overdeveloped, while they show underdevelopment in the left temporal parietal junction region. These findings of overdevelopment in the medial frontal cortex compliment the reports of deviant growth in the frontal region as reported by others (Amaral et al. 2008). The underdevelopment in the left temporal parietal junction in children with autism is of interest given the relation of this region with the emergence of self-reflection. These brain regions that show over- and underdevelopment in the autism group are those involved in various tasks of self-representation and the self in comparison to others (Frith 2001). More recently Carmody and Lewis compared the scores on self-referential behavior with some selected brain region volumes in children with ASD and found a significant association with the left temporal pole, the left temporal cortex, and the left medial prefrontal cortex, such that the greater the volume of white matter, the lower the self-referential scores (Carmody and Lewis in preparation). This demonstration in children with ASD of the relation between the left temporal region with self-recognition, personal pronouns, and pretend play adds further support for the brain

maturation hypothesis. The findings of brain region overdevelopment in frontal regions, while at the same time underdevelopment in the left temporal parietal region, suggest that autism is not a generalized delay of brain maturation but rather a variation in the timing of maturation that is specific to regions related to self-reflection.

Conclusion

Children with ASD have difficulties with self-referential behavior which is likely due to multiple causes, chiefly brain function difficulties. The failure of self-referential behavior development, either its delay or absence, has serious consequences for their social and emotional behavior, for without the self-referential abilities, a wide variety of skills which require them will be absent (Lewis 2014).

It also should be noted that the absence of these self-referential abilities – mirror recognition, personal pronoun usage, and pretense – can be used as markers which can aid in the diagnosis of autism. Given that the national average for the diagnosis of autism is still about 4 years and given that typically developing children gain these skills by 2 years, the measurement of the presence of self-referential ability can be used as an aid to early diagnosis.

Self-Report Autism Scales for Adults

Ronnie Jia¹, Zachary R. Steelman² and Heather H. Jia¹

¹Illinois State University, Normal, IL, USA

²University of Arkansas, Fayetteville, AR, USA

Synonyms

Adult Repetitive Behaviors Questionnaire-2-Revised (RBQ-2A-R); Autism spectrum condition (ASC); Autistic Spectrum Quotient (AQ-9); Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5); Systemizing Quotient (SQ-7)

Description

While diagnosticians make individual diagnoses of the autism spectrum condition (ASC) in clinical settings based on direct observations of the patients and reports by caregivers, empirical researchers seeking to gauge autistic-like tendencies in the nonclinical adult population often rely on self-

report measures, such as the *AQ-50* (Baron-Cohen et al. 2001), *RBQ-2A* (Barrett et al. 2015), and *SQ-40* (Baron-Cohen et al. 2003). These self-report autism scales and their abbreviated versions have been used as screening tools as well as in empirical research.

Despite their popularity in empirical work, they have presented either factorial validity issues (*AQ* and *SQ*), needed updating for a modern context (*SQ*), or have never been further tested using confirmatory factor analysis (*RBQ-2A*). Given their influence in the literature, it is important to ensure their psychometric validity and refine them as needed to provide rigorous and consistent measurement for future empirical researchers.

Based on three rounds of development and testing using different US and global samples from general adult populations, Ronnie Jia, PhD, Zachary Steelman, PhD, and Heather Jia, PhD reported in the *Journal of Autism and Developmental Disorders* (2019) refined versions of these self-report instruments that are psychometrically sound, parsimonious, and generalizable across nonclinical adult populations. The resulting *AQ-9*, consisting of two factors, *social communication* and *attention to detail*, now mirrors the current dual diagnostic criteria in the *DSM-5*. The *RBQ-2A-R* has now been refined through CFA for the first time. The new *SQ-7* scale also has updated content. All three refined scales demonstrate satisfactory psychometric validity and parsimony and now provide evidence of their appropriateness for empirical research.

Historical Background

To be appropriate for empirical survey-based research, a measurement instrument must possess satisfactory *psychometric validity*, such as reliability and factorial validity (Hair et al. 1998). While most researchers follow the same guidelines on scale reliability (e.g., Cronbach's $\alpha \geq 0.70$, Nunnally 1978), there has been less attention and consistency in the types of evidence required to demonstrate factorial validity (e.g.,

convergent validity, discriminant validity, measurement invariance), especially when evaluating these specific autism-related scales.

Many studies have relied on exploratory techniques, such as exploratory factor analysis (EFA) and principal component analysis (PCA), which often lead to significant over-factoring (Frazier and Youngstrom 2007), rather than confirmatory factor analysis (CFA), which can evaluate alternative a priori factor structures for the best model fit and effectively establish factorial validity (e.g., MacCallum et al. 1992). In addition to overall model fit, items should also have high loadings on the intended factors (convergent validity) and low loadings on other factors (discriminant validity). Thresholds for individual item loadings have also been recommended (e.g., 0.71 = excellent, 0.63 = very good, 0.55 = good, 0.45 = fair, and 0.32 = poor; Tabachnick and Fidell 2007). While it is critical for a factor to have at least three items (Kline 2010), it is desirable for a factor to have at least four loadings of 0.60 or higher (Guadagnoli and Velicer 1988).

Besides psychometric validity, another characteristic of a desirable measurement scale for empirical survey-based research is *parsimony*. In survey studies that include a large number of measurement items, researchers may be rightfully concerned about participants' response burden, which can lead to decreased data quality and response rates (Veale and Williams 2015). While researchers need valid measures with strong loadings and domain coverage of their focal constructs, scale parsimony is also necessary to encourage respondent participation and reduce response burden and bias (e.g., Dillman 2000).

Based on the above two key criteria (i.e., psychometric validity and parsimony), the *AQ*, *RBQ-2A*, and *SQ* are examined for their appropriateness for empirical survey-based research.

Autistic Spectrum Quotient (AQ)

The original *AQ* scale (Baron-Cohen et al. 2001) consists of 50 items in 5 factors: *social skill*, *attention switching*, *attention to detail*, *communication*, and *imagination*. Subsequent research (e.g., Austin 2005; Hurst et al. 2007; Kloosterman

et al. 2011) has recommended a three-factor model, including *social skills*, *attention to detail*, and *communication/mindreading*. However, the consistent lower reliability and convergent validity in the third factor across these studies provide cumulative evidence for a two-factor *AQ* model (*social skills* and *attention to detail*), which would be consistent with the current two-factor ASC diagnostic criteria specified in *DSM-5*: “persistent deficits in social communication and social interaction” and “restricted, repetitive patterns of behavior, interests, or activities” (American Psychiatric Association 2013). Therefore, continued evaluation and refinement of the *AQ* is needed in keeping with the current *DSM-5* criteria, which will allow for the further alignment between academic research and clinical practice.

Another noteworthy effort to achieve a parsimonious *AQ* measure is Allison et al.’s (2012) *AQ-10*, which was proposed as a rapid screening tool and was constructed by choosing the two items with the highest discrimination index values from each of the five *AQ-50* scales (Baron-Cohen et al. 2001). However, evidence for its factorial validity was not reported, and its five-factor structure is unlikely to hold in view of findings in Austin (2005), Hurst et al. (2007), and Kloosterman et al. (2011). Additionally, since each of the subscales consists of only two items, rather than the recommended thresholds of at least three items per factor (Kline 2010), they may suffer from low reliability as well as model estimation problems (Kline 2010), which can hinder their value when used in survey-based research.

Since the factorial validity of the *AQ-10* has never been reported in the literature, and the scale is frequently used in research (e.g., Jackson et al. 2018), it is necessary that its psychometric soundness be empirically tested. Despite its potential shortcomings, it has the distinct advantage of being the briefest *AQ* measure. In view of its parsimony, it was still used as a starting point for constructing a parsimonious and psychometrically sound *AQ* measure that is also theoretically linked to the *DSM-5* diagnostic criteria. (The *AQ-50* was not chosen because it is neither parsimonious nor psychometrically sound.)

Adult Repetitive Behavior Questionnaire (RBQ-2A)

The *RBQ-2A* (Barrett et al. 2015) focuses on a specific set of autism-related behaviors, i.e., restricted and repetitive behaviors. Developed using principal component analysis (PCA), it consists of 14 items in two subscales: *repetitive motor behavior* (RMB) and *insistence on sameness* (IoS). However, there is limited evidence of its factorial validity as three items have “poor” loadings ($\lambda < 0.45$, Tabachnick and Fidell 2007) and another three item loadings are in the “fair” range ($\lambda < 0.55$, Tabachnick and Fidell 2007). Given its relative newness, no follow-up research using this scale has retested and reported its psychometric properties using CFA. It is therefore necessary to further validate and refine the scale for future empirical research.

Systemizing Quotient (SQ)

The 40-item *SQ* scale (*SQ-40*, Baron-Cohen et al. 2003) was proposed as a measure of autistic tendency based on the empathizing-systemizing theory (Baron-Cohen 2002). Based on CFA results, Ling et al. (2009) found that a single-factor model for *SQ-40* has poor fit and recommended a 4-factor, 18-item solution, including *technicality*, *topography*, *DIY*, and *structure*. However, the *topography* and *DIY* subscales each had less than 3 items with “good” loadings, and overall, 8 of the 18 items have loadings that are less than “good” ($\lambda < 0.55$, Tabachnick and Fidell 2007), indicating limited convergent validity in these two subscales and the possibility that a 2-factor *SQ* model (including *technicality* and *structure*) is a better fit.

Veale and Williams (2015) tested a single-factor, eight-item measure (*SQ-8*). However, most items have lower loadings ($\lambda < 0.55$, Tabachnick and Fidell 2007). Therefore, further development of the *SQ* scale will likely require the higher loading items from the *SQ-8* to be supplemented by additional items from the *SQ-18* (Ling et al. 2009) to enhance scale validity.

In sum, though the existing *AQ*, *RBQ-2A*, and *SQ* measures have been used in many empirical studies, they still exhibit significant psychometric

issues and require additional refinement and testing to be used in future research.

Building on these prior efforts, Jia et al. (2019) reported three consecutive studies to rigorously evaluate, develop, and refine these three frequently used scales to improve their psychometric validity and parsimony as well as ensure applicability to the general adult populations. Study 1 performs a baseline examination by testing the briefest existing versions of these measures with a sample of US college students before they are refined in Study 2 through adding or removing items using a worldwide sample of adults. The scales are finally validated in Study 3 with a sample of US adult participants. These consecutive evaluations assess scale reliability, convergent and discriminant validity, factorial invariance, and nomological validity, with the aim of achieving a set of psychometrically valid, parsimonious, and consistent measures in line with established standards in the literature.

Current Knowledge

Study 1: Initial Evaluation

Method

An anonymous online survey consisting of the most parsimonious versions of the three measures, i.e., *AQ-10* (Allison et al. 2012), the *RBQ-2A* (Barrett et al. 2015), and the *SQ-8* (Veale and Williams 2015), was administered with 207 undergraduate students from 2 large public universities in the United States. All items were measured on a 7-point scale from “strongly disagree” to “strongly agree.”

Results

As expected, all five *AQ-10* subscales exhibited low internal consistency ($\alpha_{\text{Attention to Detail}} = 0.21$, $\alpha_{\text{Attention Switching}} = 0.57$, $\alpha_{\text{Communication}} = 0.50$, $\alpha_{\text{Imagination}} = 0.21$, and $\alpha_{\text{Social}} = 0.43$). When all items were evaluated in a single factor, internal consistency remained low ($\alpha = 0.48$). Both *RBQ-2A* subscales, *repetitive motor behavior* and *insistence on sameness*, achieved adequate internal consistency ($\alpha_{\text{RMB}} = 0.80$ and $\alpha_{\text{IoS}} = 0.83$), so did the single-factor *SQ-8* ($\alpha = 0.75$). Having

demonstrated adequate internal consistency (i.e., $\alpha \geq 0.70$), the *RBQ-2A* and *SQ-8* were therefore further tested for validity both within and between the scales through CFA.

When testing the *RBQ-2A* and *SQ-8* using CFA, the two scales were first examined separately. Results show that the two-factor *RBQ-2A* exhibits less than satisfactory model fit ($\chi^2 = 162.98$, $df = 76$, $CFI = 0.94$, $RMSEA = 0.074$ with 90% CI: 0.058–0.090) with the CFI below the recommended thresholds of 0.95 and $RMSEA$ exceeding 0.06 for acceptable model fit (Hu and Bentler 1999). The single-factor *SQ-8* also indicates poor model fit ($\chi^2 = 71.27$, $df = 20$, $CFI = 0.90$, $RMSEA = 0.11$ with 90% CI: 0.08–0.14), and only a single item loading exceeded 0.60.

After testing each scale individually, the two scales were examined together in a single model to evaluate their convergent and discriminant validity. The combined model also provided less than satisfactory fit ($\chi^2 = 373.19$, $df = 206$, $CFI = 0.92$, $RMSEA = 0.063$ with 90% CI: 0.053–0.073). Factor loadings indicate that four *RBQ-2A* items (RMB #1, IoS #1, #2 and #7) have “poor” loadings ($\lambda < 0.45$, Tabachnick and Fidell 2007), which are similar to those reported by Barrett et al. (2015). Thus, these four items should be removed or refined in future steps of scale development.

The *SQ-8* item loading matrix also has low loadings (items #2, #3R, and #4R) that are similar to those reported in prior research (e.g., Veale and Williams 2015), necessitating their removal or refinement in future steps. As also observed by Veale and Williams, Item 1 (“maps”) has significant conceptual overlap with Item 6 (“motorways”) and thus could be removed to increase parsimony. Since only one item has a loading exceeding 0.60, further development of the *SQ* scale requires additional items from the larger *SQ-18* to strengthen its psychometric properties.

Results from Study 1 indicate that, as expected, the *AQ-10* has low internal consistency in all of its five subscales, which likely resulted from its small number of items. Also as expected, the *SQ-8* has low item loadings and poor overall model fit. Thus, neither the *AQ-10* nor the *SQ-8* possesses

satisfactory psychometric properties for empirical survey-based research at this time. Further development and refinement of these two scales require incorporating additional *AQ-26* and *SQ-18* items to enhance their psychometric properties.

Though the *RBQ-2A* scale also exhibits less than satisfactory model fit, its psychometric properties may be improved by simply removing items with low loadings as the number of items in each factor (6 and 8) still far exceeds the recommended minimum of three items per scale (Kline 2010). Such item removal can also further improve its parsimony.

Based on the above results from Study 1, the focus in Study 2 was to improve scale validity by removing unsatisfactory items from the *RBQ-2A* and incorporating and testing additional *AQ* and *SQ* items.

Study 2: Further Refinement

Method

Data were collected from a larger, more diverse adult sample ($N = 355$ participants from 44 countries) recruited on Amazon's Mechanical Turk (MTurk) so as to enhance scale applicability and generalizability to a variety of settings. The use of MTurk data has seen significant growth in recent years in psychology, psychiatry, and other behavioral fields as a way to recruit participants that are more diverse than college students (e.g., Gosling and Mason 2015).

The survey included additional *AQ* and *SQ* items to enhance scale validity. The 6 items from the 3 retained subscales of the *AQ-10*, including *social skills* (#36 and #45), *attention to detail* (#5 and #28), and *communication/mindreading* (#27 and #31), were supplemented by 13 items from these 3 subscales of the larger *AQ-26* that had loadings of 0.40 or higher in prior research (Hurst et al. 2007). The four remaining *SQ-8* items from Study 1 (#5, #6, #7, and #8) were supplemented by six items with loadings over 0.40 from the *technicity* and *structure* subscales of the larger *SQ-18* (Ling et al. 2009). No items from its *topography* or *DIY* subscales were considered as neither factor had at least three items with sufficiently high loadings (Ling et al. 2009).

Additionally, since reverse worded items can cause respondent confusion and mistakes while failing to prevent inattentive or acquiescent answering (van Sonderen et al. 2013), three such *SQ* items were positively restated to increase clarity and improve internal consistency (#11 from “rarely” to “often”, #43 from “I would not” to “I would”, and #51 from “I do not think” to “I think”). Due to satisfactory loadings, the ten *RBQ-2A* items from Study 1 were retained.

Results

Based on the overall CFA factor loading matrix for the three measurement scales, eight *AQ* items (#5, #26, #27, #28, #31, #35, #36, and #45) with loadings in the “poor” range ($\lambda < 0.45$, Tabachnick and Fidell 2007) were dropped, before separately testing each measure. In each individual goodness-of-fit test, modification indices were used to identify and remove items that have high error covariance with other items or load onto non-intended factors (Kline 2010). This process led to the removal of another six items (*AQ* #11 and #38; *RMB* #3; *SQ* #11, #30, and #51) to further increase the psychometric properties of each scale.

After this initial refinement, the goodness-of-fit test results indicate that all three resulting scales achieved satisfactory model fit in their individual CFA tests (*AQ*: $\chi^2 = 58.29$, $df = 26$, $CFI = 0.98$, $RMSEA = 0.059$ with 90% CI : 0.039–0.079; *RBQ-2A*: $\chi^2 = 40.03$, $df = 26$, $CFI = 0.99$, $RMSEA = 0.039$ with 90% CI : 0.008–0.062; *SQ*: $\chi^2 = 19.03$, $df = 13$, $CFI = 0.99$, $RMSEA = 0.037$ with 90% CI : 0.000–0.069), along with acceptable levels of internal consistency (all $\alpha \geq 0.70$), except for *AQ attention to detail* ($\alpha = 0.67$), which is near the threshold. Further, when assessing the three scales together in a holistic model, the model fit remained satisfactory ($\chi^2 = 499.85$, $df = 260$, $CFI = 0.97$, $RMSEA = 0.051$ with 90% CI : 0.044–0.058), indicating adequate psychometric validity and parsimony with the refined scales. The three instruments, hereinafter referred to as the *AQ-9*, *RBQ-2A-R*, and *SQ-7*, were subject to a final test of their convergent and discriminant validity, nomological validity, and factorial invariance.

Study 3: Final Validation

Method

Similar to Study 2, to achieve greater scale applicability and generalizability in Study 3, a sample of 442 US adults were recruited on MTurk. In addition to the *AQ-9*, *RBQ-2A-R*, and *SQ-7* items from Study 2, scales for both neuroticism and extraversion from the Big Five Inventory (BFI, John and Srivastava 1999), which are known correlates of the *AQ* and *SQ* in prior research (e.g., Austin 2005; Schwartzman et al. 2016), were also administered for the purpose of demonstrating scale nomological validity and further evidence of convergent and divergent validity when examining the autism scales with additional constructs.

Factorial invariance tests were conducted to assess the extent to which each of these three scales is equivalent and consistent across different groups (e.g., males and females). We examined configural, metric, scalar, and complete invariance, which provide increasing levels of model strictness across groups to indicate measurement consistency (Longo et al. 2018). Though higher levels of invariance are often hard to achieve “as metric equivalence and, particularly, scalar equivalence are frequently rejected in social science research” (Cheung and Rensvold 2002, p. 601), metric invariance is considered a prerequisite for meaningful cross-group comparison (Bollen 1989).

In this study, invariance tests were conducted between male and female participants, which enable us to link our findings with existing knowledge on ASC, such as higher autistic tendencies in men than in women (e.g., Austin 2005). However, such known gender difference was also expected to make higher levels of invariance (e.g., scalar, complete) unlikely. Thus, our goal was to provide evidence of configural and metric invariance between males and females with a pattern of gender differences that are in keeping with prior literature.

Results

The CFA loading matrix for the three autism scales suggests that each scale exhibits

satisfactory convergent and discriminant validity with items loading primarily on their focal constructs and less so on the others in the model (Kline 2010). Results from three separate goodness-of-fit tests also provide evidence of satisfactory model fit:

- *AQ-9*: social communication (items #15R, #17R, #22, #44R, #47R, $\alpha = 0.92$) and attention to detail (items #6, #12, #19, and #23, $\alpha = 0.80$), with an overall model fit ($\chi^2 = 64.78$, $df = 26$, $CFI = 0.99$, $RMSEA = 0.058$, 90% CI : 0.041–0.076)
- *RBQ-2A-R*: repetitive motor behavior (items #2, #3, #4, #5, and #6, $\alpha = 0.83$) and insistence on sameness (items #3, #4, #5, and #6, $\alpha = 0.84$), with an overall model fit ($\chi^2 = 76.35$, $df = 26$, $CFI = 0.98$, $RMSEA = 0.066$, 90% CI : 0.049–0.084)
- *SQ-7*: technicity (items #5, #20, #33, and #43, $\alpha = 0.82$) and structure (items #13, #37, and #49, $\alpha = 0.73$), with an overall model fit ($\chi^2 = 20.24$, $df = 13$, $CFI = 0.99$, $RMSEA = 0.036$, 90% CI : 0.000–0.064).

Invariance tests between male and female participants indicate that all three scales showed satisfactory model fit and met the ΔCFI threshold for configural and metric invariance, but as anticipated, not scalar or complete invariance due to known gender differences also reported in prior autism research. (See Jia et al. 2019 for details.)

Also as expected, many factors within the three scales are significantly correlated with one another. As further evidence for nomological validity, they are also significantly linked to their known Big Five correlates (e.g., Austin 2005; Schwartzman et al. 2016). For example, *AQ social communication* is negatively related to extroversion ($r = -0.86$), and *RBQ-2A repetitive motor behavior* is positively related to neuroticism ($r = 0.51$).

In sum, despite the frequent use of the *AQ*, *SQ*, and *RMB-2A* in the literature, there has been limited in-depth evaluation of their psychometric properties and appropriateness for empirical

research. Three rounds of testing and refinement using heterogeneous samples from general adult populations result in three revised self-report autism scales, *AQ-9*, *RBQ-2A-R*, and *SQ-7*, that have demonstrated evidence of factorial validity (through exhibiting satisfactory convergent and discriminant validity), factorial invariance (through establishing scale configural and metric invariance across genders), nomological validity (through demonstrating intercorrelations among the three scales and with Big Five traits), as well as parsimony (all scales contain less than ten items). The resulting *AQ-9* now mirrors the current dual diagnostic criteria in the *DSM-5* and thus better aligns academic research and clinical practice. The *RBQ-2A-R* has been refined through CFA for the first time. The *SQ-7* scale consists of two factors, including *technicity* and *structure*, and its content has also been updated to remain applicable. These parsimonious and psychometrically satisfactory measures can provide efficient and consistent measurement of autistic tendencies in the general adult population in future survey research that examine relationships between autism-like symptoms and other constructs.

Future Directions

Future research should further test these instruments using new samples and in different settings. For example, these scales can be administered to the same subjects over time to assess their test-retest reliability. Though these self-report measures are not intended or designed to be diagnostic instruments for ASC, future research can employ both neurotypical and autistic samples to assess their discriminant ability and effectiveness as screening tools.

Definition

An examination of the use and efficacy of self-reported temperament to index transdiagnostic differences in reactivity and self-regulation in children and adolescents with ASD.

Historical Background

In the early twentieth century, developmental psychologists observed large groups of neurotypical children in order to describe normative sequences of motor and cognitive development. Although clear patterns emerged, what was perhaps more striking was the large amount of variability between children. Shirley (1933) described temperament as the core or nucleus of later personality. Over the ensuing decades, temperament came to be defined as early-appearing, biologically based, relatively stable individual differences in reactivity and self-regulation (Rothbart and Derryberry 1981). Individuals vary along dimensions of Negative Affectivity (e.g., fear, sadness, frustration, discomfort in response to sensory stimulation), Surgency (e.g., activity level,

enjoying novel activities, displaying positive affect, positive excitement), and Effortful Control (e.g., focusing attention, inhibiting reactions; Rothbart 2007). These three dimensions are related to the Big Five personality factors used to describe adult personality (Evans and Rothbart 2007). Individual differences in temperament act as a filter for experienced social and nonsocial environments and as such impact all aspects of a child's emerging personality including cognitions about self, others, and the surrounding physical and social world (Rothbart 2007). Furthermore, a child's temperament affects their perception of the world and, in a transactional way, the world's perception of them (Henderson et al. 2018). For example, parent perceptions of children's temperamental "difficulty" are related to differences in parent-child interactions and children's attachment representations (Seifer et al. 1996). The interplay between temperament, social perception, and social interaction forms the foundation for later personality (Rothbart 2007).

For most of the twentieth century, temperament research and theory were applied to the study of neurotypical children. However, within the last 30 years, there has been increasing attention paid to the assessment, characterization, and meaning of temperament in relation to a variety of neurodevelopmental disorders, including autism spectrum disorders (ASD). Importantly, temperament is a transdiagnostic factor that may be critical for understanding heterogeneity in symptom expression and developmental outcomes for individuals with ASD (Burrows et al. 2016; Chetcuti et al. 2019; Schwartz et al. 2009). Further, being able to quantify these individual differences opens the door to more individualized and tailored approaches to intervention, as certain strategies may be differentially successful depending on the nature of the child's temperament.

Historically, studies examining temperament in children relied on detailed and lengthy observational protocols and/or informant (e.g., parent, teacher) reports, due to concerns that children lacked the introspection and insight to accurately report on their typical behavioral and emotional reaction tendencies. There is no doubt that these approaches are highly informative. For example,

studies of the impact of observed and parent-reported early behavioral inhibition on lifecourse development have been highly influential in the fields of developmental psychology, clinical psychology, and developmental neuroscience (Asendorpf 1990; Perez-Edgar and Fox 2018). Furthermore, youth below age 8 do have significant difficulties reporting on their own abilities, due to their cognitive and language development. However, there is growing consensus that youth self-reports provide an important and unique perspective on their own internal processes (e.g., Achenbach et al. 1987; Burrows et al. 2018; Gotham et al. 2014; Moss et al. 2015). Furthermore, as youth enter adolescence, parents and teachers have less opportunity to observe the individual's behavior, and the youth themselves may have the best insight into their temperament (Achenbach et al. 1987). Importantly, there are only small to moderate associations between informant report and self-reports (De Los Reyes and Kazdin 2005; Lerner et al. 2012), highlighting the unique perspective youth self-reports contribute to the assessment of temperament.

Concerns about the psychometrics of self-reports are mirrored in the developmental disabilities literature due to a misconception that individuals with ASD do not possess sufficient language skills or insight to reflect on their own traits (e.g., Mundy et al. 2007; Tantam 2000). Thus it is critical to carefully examine the reliability and the concurrent and predictive validity of self-report measures of temperament in youth with and without ASD.

Current Knowledge

The spectrum hypothesis (Van Leeuwen et al. 2007) provides a useful model for conceptualizing and studying quantitative and qualitative similarities and differences in self-reported temperament between youth with and without ASD. Specifically, this model provides a framework for investigating whether clinical and non-clinical groups differ in (a) the psychometric properties of measures (i.e., factor structure, reliability), (b) their overall levels of temperament (i.e., mean-level

differences between groups), and (c) the nature and strength of covariation with other constructs of interest.

While the study of self-reported temperament in ASD is still nascent, several investigations have explored how individuals with ASD report on their own temperament and personality. To date, studies of self-reported temperament have found quantitative (e.g., mean-level differences) but not qualitative (e.g., psychometrics, associations with outcomes) differences in self-reported temperament in youth and adults with ASD compared to typically developing (TD) samples. Burrows et al. (2016) reported that self-reports on the Early Adolescent Temperament Questionnaire – Revised (EATQ-R), the primary measure of temperament in children, showed similar psychometric properties in youth with ASD compared to an age- and gender-matched sample of TD youth (Burrows et al. 2016). Specifically, for the broadscale domains of temperament, youth with ASD showed moderate to high levels of reliability (Cronbach's alphas ranging from 0.64 to 0.76), which was similar to TD youth levels of reliability (Cronbach's alphas ranging from 0.66 to 0.83). The two groups' estimates of reliability also overlapped on all domains, indicating that they were not reporting at differing levels of reliability. Similarly, Hesselmark et al. (2015) administered the Revised NEO Personality Inventory (NEO-PI-R) to a group of adults with ASD (with no intellectual disability) and a control group of adults without ASD or other developmental disorders. The ASD and control groups displayed comparable internal consistencies and factor structures on the NEO-PI-R. There is also evidence supporting the validity of self-reports of temperament in youth with ASD. Self-reported temperament showed similar associations with parent-reported internalizing and externalizing problems across groups of youth with and without ASD, indicating high and comparable levels of external validity of self-reported temperament (Burrows et al. 2016; Schwartz et al. 2009).

When examining quantitative differences in self-reported temperament, studies find mean-level differences across many domains of temperament. One consistent finding is that groups of

youth with ASD endorse lower Surgency and higher Negative Affect than their TD peers (Burrows et al. 2016; Samyn et al. 2011; Schwartz et al. 2009). Differences were found in all sub-dimensions of the Surgency factor (Burrows et al. 2016), indicating that youth with ASD show lower enthusiasm for high-intensity activities, have higher levels of fear/worry, and are more shy when meeting new people. Youth with ASD also self-reported higher Negative Affect in all domains, including a higher propensity for frustration, depressive mood, and frustration. There appear to be some subtle differences in Effortful Control between youth with ASD and TD peers, with Samyn et al. (2011) finding overall differences that were driven by group differences in inhibitory control and attentional control. Burrows et al. (2016) by contrast found no group differences in effortful control. These mean-level differences in temperament likely capture meaningful differences within the autism population that may partially account for the large degree of heterogeneity in comorbid psychological functioning in youth with ASD. As a transdiagnostic risk factor for a host of outcomes (e.g., anxiety, depression, ADHD), temperament may be an important early marker for later psychopathology. Quantifying differences in self-reported temperament early in development may help identify individuals who could benefit from prevention or intervention services to help reduce risk for, and impairment associated with, psychiatric comorbidities.

Another issue that has garnered considerable attention is the question of overlap between temperament and symptoms of ASD. For example, social communication symptoms core to ASD may influence an individual's levels of Surgency, with shared behavioral overlap in reduced social interest. While there may be some conceptual overlap, measures of self-reported temperament do not generally correlate with assessments of symptoms of ASD. For example, Schwartz et al. (2009) found no significant correlations between any domains of temperament and multiple measures of autism symptoms in youth with ASD. Self-reported Effortful Control also appears to be more strongly related to symptoms of attention-deficit/hyperactivity disorder (ADHD) than ASD

(Samyn et al. 2011), indicating differentiation between temperament and ASD symptoms. Certain temperamental characteristics increase risk for later behavior problems comparably in TD and ASD youth. For example, in both TD and ASD samples, behavioral inhibition and physiological reactivity to novelty are temperamental precursors to later social anxiety (SA) disorders (Bellini 2006; Clauss and Blackford 2012). In general, within samples of youth with ASD, temperament and ASD traits appear to vary widely and independently and to independently contribute to later outcomes. Understanding the unique contributions of ASD and temperament traits, as well as how they interact over time, may help explain varying developmental trajectories for children with ASD.

Future Directions

Looking forward, we believe the most theoretically and clinically relevant questions have to do with how self-reports of temperament can help explain *within-group* differences in symptom expression, psychiatric comorbidity, and adaptive functioning. Given the relatively low time and cost demands of administering self-reports of temperament, they should be a standard component of research protocols and clinical assessments. It will be particularly important to incorporate such measures into prospective, longitudinal studies to examine how and when in development self-reported temperament affects symptom expression and adaptive functioning. Similarly, it will be important to employ multimethod and multi-informant approaches to assessing temperament to identify points of agreement versus discrepancy. No study to date has investigated agreement and discrepancy between youth self- and parent-reports of temperament or identified factors that predict patterns of agreement. Investigations of this type may help determine when in development self report versus parent reports are most reliable or clinically relevant and how patterns of informant agreement/disagreement affect outcomes.

It will be important to continue designing and refining self-report temperament measures in a

way that minimizes measurement overlap with ASD symptom severity. Given the overlap between some core dimensions of temperament and ASD symptom domains (e.g., social withdrawal and avoidance), it is important to delineate between these constructs both theoretically and quantitatively so as not to artificially inflate estimates of concurrent or longitudinal associations. Some promising new directions in assessing temperament and emotion include the use of experience sampling methodologies to get self-reports of reactions to specific daily contexts, events, and stressors rather than asking participants to provide global judgments of their general reaction tendencies. Such moment-to-moment sampling techniques tend to be less susceptible to global biases and may be more manageable for youth with ASD.

Finally, conceptualizing temperament as the lens through which individuals experience their social and non-social worlds suggests that temperament may play a critical role in designing and selecting intervention approaches optimized to meet the heterogeneous needs of youth with ASD. For example, youth with ASD who are extremely high in Surgency will face significantly different challenges in the classroom than will youth with ASD who are extremely low in Surgency. Self-reported temperament could also hold great promise as a tool to assist with transition planning for youth with ASD, given the accumulating data in other fields that life course outcomes, including career satisfaction and success, are optimized for individuals who experience a good fit between temperament and environmental demands (e.g., Denissen et al. 2018).

Self-Understanding of Academic Competencies in ASD

Rosaria Furlano
Department of Psychology, Queen's University,
Kingston, ON, Canada

Definition

Self-understanding or self-perception is the ability to understand and reflect upon one's competency to perform in the world (Harter 2012). It has been established that young children overestimate their competencies (Bjorklund and Green 1992) and that this overestimation can lead to a sense of self-efficacy (Bandura 1991). As children age, they become more aware of their abilities due to an increase in acquiring cognitive abilities and social experiences that are necessary for an accurate view of the self (Harter 2012).

Research has demonstrated that children and adolescents with Autism Spectrum Disorders (ASD) overestimate their competencies above and beyond what is normative in the general population. Individuals with ASD tend to have inaccurate views of their abilities when asked about their symptomatology (e.g., Johnson et al. 2009); social functioning (e.g., Nicpon et al. 2010); and academic competencies (Furlano and Kelley 2019; Furlano et al. 2015). It is possible that deficits in specific cognitive abilities can

affect how individuals with ASD think of themselves.

Historical Background

Conceptualizations of the self have greatly evolved throughout the years and date back to the ancient Greeks. Historic philosophers (for review see Baumeister 1987) and contemporary researchers (e.g., Harter 2012) have offered different conceptualizations of the self. Of importance is James' (1890) distinction between the concepts of the "I-Self," defined as "the actor or the knower," and the "Me-Self," which refers to "the object of one's knowledge" and is a more conscious process that is related to self-esteem.

Current Knowledge

Self-Understanding Throughout the Lifespan

As previously mentioned, young children hold inaccurate views of the self (Bjorklund and Green 1992). Parenting in the first years of life may influence how children come to view their abilities. For example, caregivers often encourage young children to boast about their performances (e.g., clapping when accomplishing a task), and this acts as a means of nurturing positive views of the self (Butler 2005). Unrealistically positive views of the self continue in the preschool years (Bjorklund and Green 1992), as children at this age think of themselves using simple and observable features and have difficulty creating more general and larger views of the self (Bandura 1991). Preschool-aged children lack some of the cognitive abilities and social experiences that influence self-understanding (Harter 2012). For example, preschoolers lack the ability to engage in social comparison, which allows individuals to compare their abilities to others' (Harter 2012). Lacking the ability to engage in social comparison does not allow children to account for other people's performances, which can cause them to overestimate their competencies (Ruble et al. 1980).

Self-understanding becomes more accurate in middle to late childhood, as children at this age are able to differentiate between abilities across domains (for review see Harter 2012). For example, older children will often understand that they are better at one academic subject compared to another. Children and adolescents also have the ability to engage in abstract thinking and self-understanding, which allows them to describe their abilities as higher-order representations of the self in form of trait labels (Harter 2012). For example, older children and adolescents are able to understand that doing well in academic courses such as math, science, and geography fall under the trait label of “smart” (Harter 2012). Self-understanding continues to be mostly realistic in late adolescence and adulthood; however, there is evidence suggesting that most adults tend to think highly of themselves (e.g., Taylor and Brown 1988). Social psychology research has demonstrated two well-known phenomena related to self-understanding in adults. First, there is the “better-than-average” effect, where individuals evaluate themselves as being more skilled when comparing themselves to an average target (Alicke and Govorun 2005). Individuals also display an optimism bias where they believe that they are less likely than others to experience a negative event and have unrealistic optimism about the future (Alicke and Govorun 2005).

Self-Understanding in ASD

Self-referential behaviors, which can be viewed as developmental prerequisites for self-understanding, are examined in young children using mirror recognition tasks, personal pronoun use, and other-directed pretend play (for review see Lewis et al. 2016). While typically developing (TD) children display these behaviors around 2 years of age (Lewis and Ramsay 2004), self-referential behaviors tend to be absent or delayed in children with ASD (Lewis et al. 2016). Children with ASD have difficulty using personal pronouns (e.g., Lee et al. 1994) and also tend to choose to participate in self-directed play rather than playing with others (Charman and Baron-Cohen 1997).

Research has begun to examine how individuals with ASD understand their competencies. The majority of research has focused on examining how children and adolescents with ASD think of their own symptomatology and social functioning. For example, Johnson et al. (2009) found that children and adolescents with ASD described themselves as having fewer autistic traits and more empathy as compared to parental reports. Research has also demonstrated that individuals with ASD are not aware of the scope of their social deficits and tend to overestimate their social competence compared to parental and teacher reports (Vickerstaff et al. 2007).

Self-Understanding of Academic Competency in ASD

Previous research in the field has focused on examining self-understanding in areas in which individuals with ASD inherently have difficulty. Very few studies to date have examined self-understanding of academic abilities. Basic academic skills (i.e., reading, math, and writing) in children and adolescents with high-functioning ASD (full-scale IQ above 70) tend to be intact and relative to IQ scores (Mayes and Calhoun 2008). Academic difficulties in individuals with ASD mainly lie in areas related to organization, attention, and complex processing, and children and adolescents with ASD have been found to have deficits in listening and reading comprehension (Whitby and Mancil 2009).

Recently, research has demonstrated that individuals with ASD tend to overestimate their academic competencies when they were asked how they performed on basic academic tasks. Furlano et al. (2015) assessed how self-understanding of academic abilities in children and adolescents with ASD, aged 12–18 years, differed from TD peers. In order to test self-understanding, two objective academic tasks, a verbal and a math task, were used (Furlano et al. 2015). Participants were asked to predict how they thought they would perform before the task and how they thought they performed after the task (Furlano et al. 2015). Self-understanding was examined by comparing the participant’s perceived score on the tasks

to their actual score (Furlano et al. 2015). Using the participant's actual score on the task as a criterion measure reduced any bias associated with parental report, which is typically used in self-understanding research, and also allowed participants to self-evaluate their competencies on concrete tasks that they encounter on a daily basis in school (Furlano et al. 2015). The results of the study demonstrated that while there were no differences between the ASD and TD groups' performance on the actual task, meaning that their academic abilities did not differ, the ASD group overestimated their competencies both before and after completing the task compared to the TD group (Furlano et al. 2015).

Furlano and Kelley (2019) replicated and built upon these results by examining whether self-understanding of academic abilities in children with ASD differ compared to TD controls and whether estimations of competency change after providing feedback on the task. Feedback is regularly used in academic settings and has been shown to increase self-efficacy and academic achievement (Pajares and Schunk 2001). The ability to process feedback is important as it helps individuals monitor their strengths and weaknesses, which in turn allows them to focus on the areas that they may have difficulty in (Grainger et al. 2014). Individuals with ASD have been shown to be able to process external and concrete feedback similarly to TD peers; however, they have difficulty in understanding more social and abstract feedback, such as a high five (Ingersoll et al. 2003). As such, Furlano and Kelley (2019) sought to examine if individuals with ASD would be better able to track and update their estimations of their own competencies when they were given feedback on how they performed on each question of an academic task. The results of the study demonstrated that compared to the TD group, the ASD group overestimated their performance on academic tasks when they were asked to predict their performance before and after each task, except when they were given feedback (Furlano and Kelley 2019). The ASD group's estimations of their performance became more accurate when they were given feedback compared to when they were not, which suggests

that they are able to process feedback and track and update their evaluations (Furlano and Kelley 2019). Overall, the results of these two studies (Furlano and Kelley 2019; Furlano et al. 2015) suggest that children and adolescents with ASD overestimate their academic competencies even after completing concrete tasks that they encounter on a daily basis in school, and this overestimation of competency is above and beyond what is normative in the general population. This suggests that individuals with ASD have deficits in the self-understanding of their academic competencies, a domain in which they do not have inherent deficits.

Factors Influencing Self-Understanding in ASD

Harter (2012) suggests that both cognitive abilities and social experiences shape how an individual thinks of their competencies. Although very little empirical research has been conducted on how specific factors relate to self-understanding in ASD, there are some potential theoretical explanations that may account for why individuals with ASD tend to overestimate their academic competencies.

Cognitive abilities. Cognitive abilities play an important role in shaping how individuals think of themselves. The overestimations of competency seen in young children have been attributed to cognitive limitations (Harter 2012). Young children lack certain cognitive abilities that are required to process an accurate view of the self (Harter 2012). As such, it is possible that cognitive ability deficits seen in individuals with ASD may cause them to lack understanding of their own abilities.

Theory of mind. It has been well-established that many individuals with ASD, including those with high-functioning ASD, experience difficulties in theory of mind, which is the ability to attribute mental states to others (Baron-Cohen et al. 2001). Researchers have suggested that the same cognitive mechanisms that underlie theory of mind understanding are same as those that are required for attributing mental states to the self (Frith and Happé 1999). Theory of mind understanding allows for individuals to utilize opinions

that other people have of them in order to create a view of the self (Selman 2003). The inability to understand that others may be critical of you can lead to individuals to have overly positive views of the self (Harter 2012).

Metacognitive monitoring. Metacognitive processes are inherently related to understanding the self. Flavell (1979) broadly defined metacognition as “cognition about cognition” or “thinking about thinking,” and his original model was comprised of two components: metacognitive knowledge and metacognitive monitoring. Metacognitive knowledge is acquired world knowledge that relates to cognitive matters, whereas metacognitive monitoring refers to how an individual manages their knowledge and is used to control cognition to meet a goal (Flavell 1979). It has been suggested that children with ASD have difficulties with more complex academic tasks due to deficits in metacognitive monitoring (Grainger et al. 2014). Deficits in metacognitive abilities would make it difficult for individuals to introspect and activate mental representations about the self (Lyons and Zelazo 2011). More specifically, it would be difficult for individuals with metacognitive monitoring deficits to keep track of their performance during academic tasks, which would affect how they evaluate their achievements.

Executive functioning. Executive functioning is an umbrella term for cognitive processes that control behavior, such as planning, working memory, attention, problem-solving, verbal reasoning, and inhibition (Ozonoff et al. 1991). Research has suggested that individuals with ASD have difficulties with cognitive flexibility (Ozonoff et al. 1991) and inhibitory control (Russell et al. 1996). Both of these processes may affect how individuals think of themselves. Deficits in cognitive flexibility, which is the ability to switch back and forth between concepts, can make it difficult for individuals to conceptualize errors during a task (Ozonoff et al. 1991). Having poor inhibitory control may make it difficult to control responses when answering self-evaluations (Owens et al. 2007).

Episodic memory. Episodic memory is memory for a specific event that happened at a certain

time and place (Tulving 1972). Individuals with ASD have generally been shown to excel at tasks that involve semantic memory (i.e., rote memorization; Bennetto et al. 1996) but display impairments in episodic memory (Lind and Bowler 2009). It has been suggested that there is a dynamic relation between episodic memory and the self where the events that individuals recall shape how they view themselves (Tessler and Nelson 1994). For example, when individuals are asked how they are at math, they generally attempt to recall their performance on a previous math task. Researchers have challenged the link between episodic memory and self-understanding by arguing that individuals have self-schemas that are retrieved without having to reference memories (Sedikides and Spencer 2007). However, these self-schemas typically exist in adults, who have more stable views of the self, compared to children who are constantly updating and building their view of the self (Wheeler et al. 1997). As such, it is possible that deficits in episodic memory may contribute to individuals with ASD inaccurately reporting their abilities.

Social experiences. While it has been suggested that the deficits possessed by individuals with ASD have in self-understanding are due to difficulties in specific cognitive abilities, it is also important to consider the role of social experiences. One socially motivated factor that may influence how an individual reports on their abilities is self-enhancement. The “better-than-average” effect and optimism bias seen in adults are said to be influenced by self-enhancement motives (Taylor and Brown 1988). Individuals may overestimate their competencies when asked about their abilities in order to hide difficulties and display confidence (Harter 2012). While self-enhancement motives may underlie self-understanding in TD individuals, overestimations seen in ASD may not be deliberate and are instead linked to impairments in specific cognitive abilities that are necessary for accurate self-understanding.

Self-Understanding in ADHD

A closely related population that has consistently displayed deficits in self-understanding is

individuals with attention deficit hyperactivity disorder (ADHD; Owens et al. 2007). Research has previously shown that 31% of children with ASD meet diagnostic criteria for ADHD and 24% meet subthreshold clinical ADHD symptoms (Yerys et al. 2009). The *DSM-5* now allows for a co-diagnosis of ADHD and ASD (APA 2013), and it has been suggested that there is a degree of overlapping traits between the ASD and ADHD diagnostic criteria (Mazefsky et al. 2012). Much like children with ASD, children with ADHD display difficulties in social deficits and behavior problems (Pelham and Bender 1982). Children with ADHD tend to have fewer close friendships and are more rejected in the classroom compared to their TD peers (Pelham and Bender 1982). A large body of literature suggests that despite having chronic difficulties in academics, many children and adolescents with ADHD tend to overestimate their academic competencies in comparison with other criteria, such as parental report, teacher report, and other more objective criteria of competency (for review see Owens et al. 2007).

There are several theoretical explanations for why children and adolescents with ADHD tend to overestimate their competencies in a variety of domains. Firstly, it is possible that some of the inherent deficits that exist in both the ASD and ADHD diagnosis contribute to overestimations of competency. For example, both children with ADHD and ASD have difficulty with planning, attention, problem-solving, and inhibition (Ozonoff et al. 1991). Another possible explanation is the self-protective hypothesis, which suggests that when children with ADHD are threatened by a task, they attempt to hide their incompetence by exaggerating their abilities (Owens et al. 2007). This hypothesis suggests that children with ADHD use these overestimations of competency as defense mechanisms that helps to protect their self-esteem (Evangelista et al. 2008). In sum, it is possible that both of these populations are overestimating their competencies due to overlapping cognitive deficits that are inherent in both diagnoses, or it is possible that individuals with ASD have impaired self-understanding due to unique cognitive deficits,

while individuals with ADHD do not have impaired self-understanding and overestimate their abilities to protect their self-esteem.

Future Directions

Future research on self-understanding of academic competencies in individuals with ASD should focus on two main questions. First, researchers should empirically examine factors that underlie this phenomenon. As mentioned, it is possible that individuals with ASD are unaware of their competencies and overestimate their abilities because they lack certain cognitive abilities that are necessary for accurate views of the self (Harter 2012). This is further evidenced by the fact that children and adolescents with ASD overestimate their competencies even when they are asked to reflect on their performance on concrete academic tasks that they experience in school (Furlano and Kelley 2019). Future research should empirically investigate how cognitive abilities, which have been theoretically linked to self-understanding (i.e., theory of mind, metacognition), relate to the overestimations of competency. Different methodology to examine self-understanding of academic competencies should be used. It is possible that more concrete and simple estimations of academic competency (i.e., asking participants how many questions they answered correctly on a task; Furlano and Kelley 2019) may be more related to metacognition, while more abstract broader questions of the self (i.e., asking participants to select a description that fits their abilities; Harter 1985) may be more related to episodic memory.

It is also vital to understand the influence that holding overly positive views of the self can have over time. There exists conflicting evidence on whether having enhanced views of the self is beneficial or detrimental. In childhood, having a positive view of the self is beneficial as it can help children to persevere through difficult tasks regardless of outcome (Taylor and Brown 1988). This is especially helpful in an academic domain, as it promotes children's willingness to try even after failing to succeed (Taylor and Brown 1988).

However, some research suggests that having overly positive views of the self can have negative implications in clinical populations. For example, overestimations of competency have been found to lead to conduct problems in children with ADHD (McQuade et al. 2011). Children with ADHD tend to react negatively when they are given realistic feedback that does not correspond to how they view themselves (McQuade et al. 2011). Research has also shown that individuals with Obsessive Compulsive Disorder who have greater insight into their symptoms show more readiness for treatment (Storch et al. 2008). It is therefore possible that having a positive view of the self in terms of academic competencies may be beneficial in children with ASD, as it can help them continue to be motivated on academic tasks even if they have not previously done well on a similar task. However, this overestimation of academic competency may not be helpful past childhood. For example, if adolescents and adults are not aware of their strengths and weaknesses, it may cause them to make poor choices about their education and future career path. Overall, future research should continue to examine self-understanding in ASD and should examine the consequences of overestimating academic competencies throughout the lifespan using longitudinal studies.

Semantic Fluency

► Verbal Fluency

Semantic Memory

Dermot Bowler and Sebastian Gaigg
Autism Research Group, City University London,
London, UK

Definition

The concept of semantic memory, along with episodic memory, forms part of the declarative memory system, the operation of which is open to conscious awareness. It encompasses an individual's stock of general knowledge. Although traditionally thought of as storing information in an abstract, propositional manner that transcends the perceptual features of the information it represents, more recent formulations acknowledge some enduring representation of the original sensory or perceptual information. Semantic memory is organized in a way that permits flexible goal-directed retrieval and utilization of the stored information, and its operation is accompanied by a particular state of conscious awareness that does not involve the self reexperiencing the past. In this respect, it contrasts both with episodic memory, in which conscious awareness involves the self, and with procedural memory, which is not accessible to conscious awareness.

Historical Background

Most authorities now agree that human memory can be divided into “non-declarative” systems, such as sensory or procedural memory, whose operation is relatively inaccessible to conscious awareness, and “declarative” systems, which represent the conscious act of “remembering something.” A major distinction within the declarative memory system is that between semantic and episodic memory (see Gardiner 2008 for review). The term “semantic memory” emerged from the literature on experimental, laboratory-based studies of memory in the 1960s and 1970s and was systematically elaborated in a chapter by Tulving

(1972). Tulving has become the scientist most famously associated with the term “semantic memory” and its relation to other memory systems, in particular episodic and procedural memory (see Tulving 1985 for review). Although dividing memory along these lines is not universally accepted (see Squire 1987 and Jacoby 1988 for alternative accounts), it is largely to the work of Tulving that we owe the idea of a separate, semantic memory system that handles and organizes our store of factual general knowledge about the world.

Tulving (1972) defined semantic memory as “. . . the memory necessary for the use of language. It is a mental thesaurus, organized knowledge a person possesses about words and other verbal symbols, their meaning and referents, about relations among them and about rules, formulas, and algorithms for the manipulation of these symbols, concepts and relations” (p. 386). Tulving (1985) contrasts this semantic memory system with the episodic memory system, which stores events as situated in time, rich in perceptual and contextual detail and related to a sense of the experiencing self. In a later account, Tulving (2001) refers to semantic memory as a store of “timeless facts” that are accompanied by *noetic conscious awareness*. This awareness is not tied to a particular time or place and does not involve a sense of the self as knower even though it may contain propositions about the self (I am a psychologist, I have a cat, etc.). Episodic memory, by contrast, involves “mental time travel” where the self travels back in time to recreate the temporal and spatial context of the recollected episode and is accompanied by *autonoetic conscious awareness*, which is associated with a specific place and time and involves a sense of self as the knower of the recollected information.

The reasoning that led Tulving (1972) to argue for separate semantic and episodic memory systems rests on a number of observations and distinctions that are still relevant to attempts to characterize the structure of the human information processing system and which are also relevant to an understanding of autism spectrum disorder (ASD). A key distinction between

episodic and semantic memory lay in the way information was stored in the two systems. Whereas Tulving argued that episodic information is stored in terms of the perceptual attributes of items information and the relation of directly experienced items to each other in space and time, information in semantic memory is more abstract and propositional in nature. Although a representation in semantic memory may contain elements of the original, perceptual features of the information on which the memory is based (e.g., registering that water is a liquid), the way this information is represented is biased more toward the logical implications of the proposition “water is a liquid” than to any perceptual experience of wetness or fluidity that might be encountered in a direct experience of drinking a glass of water.

In the four decades since the term became current in discussions of memory, research has been aimed at further characterizing the structure and function of the semantic memory system. Some investigators have attempted to confirm or challenge the semantic/episodic distinction at both a behavioral and a neural level. Of more relevance to the study of ASD, however, is research that has concentrated on how information in the semantic memory system is organized.

It is of considerable advantage to an organism if its store of knowledge (facts, propositions, etc.) can be organized and linked together in various ways. Such organization means that each stimulus, object, or event is not seen in isolation but that groups of stimuli can be treated similarly, thus achieving savings in information processing load. One form such organization can take is for objects and events to be grouped into categories or concepts, which in turn can be further grouped hierarchically. For example, HAT, COAT, SHOE, and SCARF can all be thought of as “items of clothing,” just as CAR, BICYCLE, BOAT, and TRAIN can be grouped under the heading “modes of transport.” These two superordinate categories further contrast with “animals” and “fruit” in being artifacts rather than natural kinds. Words can also be related associatively, for example, by tending to occur together. So BED, PILLOW, BLANKET, SNOOZE, and NIGHT can be

thought of as “going together” because they are all strongly associated with the word “SLEEP.”

Attempts to formulate theories of concept formation and representation have come from philosophy, neurology, experimental psychology, and neuroscience (see Murphy 2002, Chap. 1 for review). *Classical concept theory* proposes that all higher-order concepts can be fully defined by feature combinations that are individually necessary and jointly sufficient to define an exemplar of that concept. Accordingly, we might say that birds are warm-blooded, have feathers and wings, lay eggs, and can fly. However, classical concept theory encounters a number of difficulties, both at a logical and a psychological/neuropsychological level. For example, penguins are birds, yet they do not fly, raising the question of what constitute necessary defining features of the category “bird.” Also, researchers have grappled with the question of how an abstract, multidimensional concept such as “bird” can be represented in the brain, given that it derives from an aggregate of different perceptual features from different sensory modalities (appearance, sound, feel, etc.). In an attempt to overcome some of these objections, *prototype theory* argues that concepts comprise averaged-out representations of a range of instances of members of the concept or category, weighted by their frequency of occurrence in the real world. Thus, a prototype of a bird might add “can fly” to the properties listed earlier but not posit this as a necessary condition for being a bird (e.g., think of ostriches or penguins). More recently, theorists such as Barsalou (2008) have argued that the organization of representations of the world is grounded in our physical, embodied experience of that world and that this organization will ultimately reflect the features of the situated, embodied groundedness that engendered them. For example, Marques (2006) asked participants to verify statements such as (1) *a dog can bark*, (2) *a bee can buzz*, and (3) *a horse has hooves*. They found that verification time increased when a statement followed 1 in a different modality (statements 1 and 3 involve a switch from audition to vision) than when it followed 1 in the same

modality (statements 1 and 2 both involve audition). They concluded that this demonstrated the lasting effects of perceptual modality on conceptual reasoning.

Although much of the discussion around prototype and grounded theories of conceptual representation does not explicitly consider how concepts are actually represented in the brain, the question of how such representations are implemented is a growing area of research. Of particular relevance to ASD is research into the extent to which representations in semantic memory are amodal and completely abstracted from their initial sensory and perceptual origins or unimodal, tied to modality-specific representational systems or multimodal, retaining features of all modalities involved in the laying down of the representations (see Gainotti 2006 for review).

Some researchers such as Lambon Ralph and Patterson (2008) argue for there being an “amodal semantic hub” at which categories are represented across all modalities that contributed to the generation of that category. Other researchers, such as Damasio (1989) argue that the multimodal, multisensory activations generated when an object is encountered are coded hierarchically in the nervous system in a way that generates higher-order representations that continue to retain some of the original sensory/perceptual information. What Damasio terms “higher-order convergence zones” become more or less hierarchically organized in ways that reflect the organism’s experience of objects in the real world.

From this brief overview, we can see that the original notion of semantic memory, that of a consciously accessible, organized set of pieces of information about the world that is separate from but interacts with our recollection of the personally experienced past, is still current, if not entirely uncontroversial. The information it contains is, to a greater or lesser extent, abstracted from the sensory information that initially gave rise to it, and when it is retrieved, it is accompanied by a state of conscious awareness that does not involve the self in reliving past episodes.

Current Knowledge

One of the most enduring discoveries in the science of autism spectrum disorder (ASD) is the observation by Hermelin and O'Connor (1970) that the disorder consists of a difficulty with the meaningful encoding of stimuli. That observation was made at a time when the concept of semantic memory was beginning to emerge in the mainstream experimental psychology literature. In the intervening four decades, much more has been learned both about the organization and functioning of human memory in general and about the patterning of other psychological functions in ASD, yet the core of Hermelin and O'Connor's observation – that being on the autism spectrum implies a difficulty in keeping an abstract, verbally mediated, systematically organized store of knowledge that can be drawn upon to guide action – continues to have considerable validity.

The three aspects of semantic memory outlined in the *Historical Background* section each have their implications for the operation of the system in individuals with ASD. There is now a considerable weight of evidence to support the idea that individuals from all parts of the autism spectrum experience some difficulties with the structural organization of the semantic memory system. Although early studies of categorization abilities in children with intellectual disability (ID) and ASD revealed intact basic and superordinate categorization skills, electrophysiological signatures of superordinate categories were found to be atypical. Moreover, whereas children with ASD and ID have been shown to be unimpaired in sorting a set of shapes under appropriate shape headings, they were impaired in sorting a set of objects into the categories of trees, beds, human figures, animals, tools, and vehicles. Moreover, their ASD group was impaired on a class-inclusion task where they had to answer questions like “are all the circles red?” (See Bowler 2007, Chap. 7 for a more detailed review of this work).

A further set of findings have shown that memory in ASD is less influenced by meaningful relations among studied items. This is especially true

in tasks such as free recall, where the test procedure provides few clues to the studied material. One measure of sensitivity to the semantic structure of studied material is the extent to which words from the same category are clustered together at recall even though they were randomly distributed through the study list. The overwhelming majority of studies of children and adults with ASD show diminished categorical clustering of items in free recall. Children with ASD and significant intellectual disability (ID) also make less use of sentence structure and categorical relations to aid their free recall of lists of words. For example, children without autism show better recall of the sentence *where is the ship* than the random string *wall long cake sand*. Recall by children with ASD, matched with the non-ASD children on digit span, has shown no difference between the two types of material. Studies have also shown that children without ASD recall more words from a list where each word is the name of an animal than from lists where each word came from a different category. Children with ASD matched with the typical children on verbal mental age showed no advantage for the animals list, an observation that also holds for higher-functioning adults with ASD. This difficulty in exploiting categorical semantic relatedness also extends to the recall of incidentally encoded context. When high-functioning adults with ASD are asked to study words inside a rectangle when there are also conceptually related or unrelated words outside the rectangle, they do not show enhanced free recall of words that are studied in conjunction with semantically related words. Comparison participants without ASD, by contrast, show enhanced recall when both words (inside or outside the rectangle) are related (see Bowler 2007, Chap. 7 for a detailed review of these studies).

Difficulties with exploiting structural semantic relations to aid recall appear at first sight to be contradicted by demonstrations of intact illusory memories in individuals with ASD (see Bowler et al. 2011 for review). These studies typically ask participants to study lists of words that are strong associates of a non-studied word (such as the

BED, PILLOW, BLANKET... example given earlier) and then test recognition of studied words and non-studied words including the strong associate SLEEP. However, as Bowler et al. (2011) observe, tasks requiring the exploitation of hierarchical semantic relations differ in their computational demands from those that require a grasp of associations between pairs of items. Bowler et al. draw a parallel between the kind of reasoning involved in illusory memories and the processing of what Halford (1992) has termed *binary relations*, in which two items of information must be processed simultaneously. Exploiting hierarchical semantic relations to aid recall involves *ternary relations*, in which successive studied words (say APPLE, HORSE, PEAR) need not only to be compared to each other but also to the higher-order categories under which they are subsumed.

One reason why relational complexity may be difficult for individuals with ASD is that it may result from a bias or preference for item specific rather than relational processing. When adults with ASD and typical participants are asked to recall lists of items made up of categories, each of which is represented by between 2 and 16 exemplars, ASD participants' recall of the smaller categories is impaired, suggesting that they are less likely to notice the links between items from categories represented by small numbers of items widely spaced in the study list (imagine studying a list of 42 words and encountering *apple* among the first few words and *pear* among the last few). Orienting participants to relations among items by sorting them into categories at study aided recall in both groups of participants but was less effective for the ASD group. Orienting them to specific features of items by asking participants to rate each item's pleasantness was more effective in enhancing recall in the ASD group. These findings suggest a bias in ASD toward processing individual item features and away from relations among items. This in itself will militate against the kinds of complex relational strategies needed to recruit hierarchical category structure in the aid of recall (see Bowler et al. 2011 for further elaboration).

The explanation of difficulties in recruiting semantic relatedness to aid recall in terms of

processing complexity helps to flesh out the observation by Minshew and colleagues (2001) that individuals with ASD experience greater difficulties with complex but not simple memory tasks. But both accounts beg the question of how and why such difficulties with complexity might come about. An answer to this question may well be provided by a reconsideration of how Tulving (1972) originally described the laying down of semantic memory traces. He emphasized the abstract, propositional nature of semantic traces, which were not closely tied to the original sensory-perceptual information that gave rise to them. We have already seen that more recent theorists have taken different perspectives on the extent to which semantic memories are distanced from their sensory, perceptual, and embodied origins, but all acknowledge some level of abstraction from the sensory data (see Gainotti 2011). The bias seen in ASD toward item-specific processing is consistent with the view that the principles governing the organization of semantic memory in this population may well reflect a greater contribution from sensory and perceptual data.

One theory of conceptual representation that has been researched in the context of ASD is prototype theory, which, as we have seen, proposes that abstract representations of semantic categories are built up as averages of the features of the examples of members of that category. The balance of existing experimental evidence suggests that at least a subset of individuals on the autism spectrum have some ability to abstract perceptual prototypes (Molesworth et al. 2005) but can take longer to do it. This last finding can be explained in terms of the *enhanced perceptual functioning* (EPS, Mottron et al. 2006) account of ASD, which argues that individuals with ASD, although as capable as typical individuals of generating global, abstract representations of stimuli, continue to hold lower-level perceptual representations of learned material. The presence of these lower-level representations is argued to affect both the speed and extent to which prototypical representations are abstracted. The EPS may also help to account for why individuals with ASD appear to organize stored information in a

different way from typically developed individuals. Bowler et al. (2008) asked participants with and without ASD to recall a list of 16 unrelated words presented over 15 trials, with the words presented in a different order on each trial. One of the principal aims of the study was to ascertain the amount of *subjective organization* engaged in by participants, i.e., the extent to which the structure of each participant's recall became similar across trials and, as a consequence, differed from the order of the presented words. An index was also calculated of the degree to which subjective organization converged among individuals across trials. Bowler et al. (2008) found that whereas their ASD participants showed only slightly diminished subjective organization, the extent to which this organization converged across individuals over trials was significantly less than in the comparison participants. This suggests that as a group, the ASD participants were organizing the studied material differently from each other, whereas the typical group was showing increasing similarity in their organization of the material. Taken together with the EPS theory and with the observations on diminished clustering in recall of categorized lists mentioned earlier on, this finding suggests that the way that ASD individuals organize items in memory may be more diverse and not as biased toward abstract, semantic aspects as in typical individuals. Memory organization in ASD might rely to a greater extent on perceptual features of studied material, such as rhyme, number of syllables, or form of the word in the case of written studied material. Such conjectures have yet to be tested empirically.

A final, important aspect of semantic memory system centers on the kind of conscious awareness that accompanies its operation. Both familiarity and the noetic conscious awareness or experience of "timeless facts" referred to by Tulving can be measured in recognition memory experiments by asking participants to make an additional "remember/know" judgment once they have identified a test word as having been encountered in the study phase. Participants are told to make "remember" responses when they have the experience of reliving the studied episode (reflecting autonoetic consciousness) and "know" responses when they

have a strong sense of having encountered the word previously (reflecting noetic awareness) but without distinct recollection of the episode. A large number of studies have now demonstrated diminished episodic "remembering" accompanied by undiminished semantic "knowing" in high-functioning adults with ASD. Moreover, a series of manipulations that are known to enhance or diminish the level of "remember" or "know" responses in the typical population yielded similar effects in an ASD group, suggesting that processes underlying these responses, although quantitatively different, are qualitatively similar in the two groups. These findings suggest that individuals with ASD utilize their semantic memory system to compensate for episodic difficulties, an observation that is borne out by studies of autobiographical memory, where individuals with ASD characteristically report autobiographical events in terms that suggest items of factual knowledge rather than personally experienced, relived events (see Bowler et al. 2011 for review). However, the research reviewed earlier, showing enhanced perceptual involvement in semantic memory representations, suggests that the semantic memories of ASD and non-ASD individuals may be qualitatively similar only up to a point.

Insofar as semantic memory consists of a stock of knowledge about the world, individuals with ASD without accompanying intellectual impairment appear to have an intact store of factual material. Where they appear to differ is in the way that this information is recorded and manipulated. Semantic memories in ASD appear to be tagged with more of the sensory and perceptual information from the original source of the memories, which seems to promote a more item specific rather than a relational approach to processing the material. This has important consequences in any task that requires the flexible deployment of semantic relations for its successful resolution.

Future Directions

Future research needs to address the following points:

1. Establish the basis on which individuals with ASD organize information in semantic memory.
2. Determine the brain bases of such organization both in terms of processing at encoding and retrieval and in terms of storage.
3. Work out the implications of atypical encoding, storage, and retrieval on the way semantic information is utilized in adaptive functioning.
4. Investigate ways to overcome any negative consequences of atypical operation of the semantic memory system.

Short Description or Definition

“Semantic pragmatic disorder” is a term that describes individuals with a communicative profile characterized by relatively intact structural language (phonology, morphology, syntax) but with abnormalities in language content and use. Communicative behaviors commonly observed in semantic pragmatic disorder are listed below (Rapin 1996):

- Verbosity
- Comprehension deficits for connected speech
- Word finding deficits
- Atypical word choices
- Phonology and syntax unimpaired
- Inadequate conversational skills
- Speaking aloud to no one in particular
- Poor maintenance of topic
- Answering besides the point of the question

Categorization

In the mid-1980s, two taxonomies of developmental language disorders were independently published, one in the USA (Rapin and Allen 1983) and the other in the UK (Bishop and Rosenbloom 1987). Both described a subtype of developmental language disorder in which the primary impairment was in language content and use. Rapin and Allen termed this language profile “semantic pragmatic deficit syndrome,” and Bishop and Rosenbloom used the term “semantic pragmatic disorder.” Since the early 2000s, there has been a transition to the alternate label of pragmatic language impairment (or PLI), particularly in the UK, after evidence that semantic and pragmatic deficits do not always occur in combination (Bishop 1998).

Semantic pragmatic disorder contrasts with specific language impairment, in which there is primary impairment in the structural aspects of language, and with autism spectrum disorders, which includes a raft of behavioral difficulties such as social impairments and restricted and repetitive behaviors. However, a number of studies have shown that the diagnostic boundaries between these conditions are not clear-cut; some children with SLI exhibit pragmatic difficulties, and some children with semantic pragmatic disorder present with one or more autistic features (Bishop and Norbury 2000). Although semantic pragmatic disorder is not included in either the DSM-IV-TR or ICD-10 classification systems, it remains a relatively common diagnosis for language-impaired children in North America, Europe, and Australasia. The DSM-V proposes a new diagnostic entity, Social Communication Disorder, with diagnostic criteria that is highly similar to descriptions of Semantic Pragmatic Disorder.

Epidemiology

There has been no epidemiological study of semantic pragmatic disorder in the general population, and therefore, the incidence and prevalence of the condition remain unclear. However, it is

estimated that these children make up a significant minority of the language disordered population, with a large study in the UK finding that 25 of 242 children (10.3%) displayed characteristics of semantic pragmatic disorder (Conti-Ramsden and Botting 1999).

Natural History, Prognostic Factors, and Outcomes

One study has chartered the adult outcome of individuals diagnosed with semantic pragmatic disorder in childhood (Whitehouse et al. 2009a, b). The pattern of communication difficulties observed in childhood was found to persist to adulthood, and the adults with semantic pragmatic disorder had enduring difficulties with language use but presented with relatively intact language and literacy skills. The adults with semantic pragmatic disorder were more academically able than a comparison group of adults with specific language impairment, and all had obtained some form of tertiary education. However, while the vast majority of these adults demonstrated a range of independent behaviors, few had experienced close friendships or romantic relationships.

Clinical Expression and Pathophysiology

There is considerable debate as to whether semantic pragmatic disorder is best viewed as a subtype of developmental language disorder or an extension of pervasive developmental disorder (Boucher 1998). Evidence that some children have poor pragmatic language ability without additional autistic symptomatology (Botting and Conti-Ramsden 1999) has led to suggestions that semantic pragmatic disorder may fit a profile intermediate between specific language impairment and autism (Bishop and Norbury 2002).

Little research has investigated underlying biological mechanisms that may be associated with a diagnosis of semantic pragmatic disorder. Woodhouse et al. (1996) examined head circumference in 11 children with semantic pragmatic disorder and found that all had a head

circumference that exceeded the 90th percentile for their age, a finding that draws parallels with the widely observed acceleration in head circumference growth among children with autism (Redcay and Courchesne 2005).

An increasing number of studies have investigated biological associations with pragmatic language skills either among individuals with autism and their relatives or within the general population. Family studies indicate that pragmatic difficulties appear to be a heritable trait and are often observed among relatives of autism probands to the exclusion of any other autistic-like trait (Landa et al. 1992; Whitehouse et al. 2007, 2010a). Molecular genetic studies have started to pinpoint loci associated with pragmatic language ability, such as the short arm of chromosome 5, which was found to be associated with scores on the social communication subscales of the Children's Communication Checklist in a general population sample of 10 years of children in the UK (St. Pourcain et al. 2010). Recent studies have also indicated an association between exposure to increased levels of prenatal testosterone and pragmatic language difficulties among otherwise typically developing children (Whitehouse et al. 2010a), though this finding was not replicated in a different cohort (Knickmeyer et al. 2005).

Evaluation and Differential Diagnosis

Three methods are commonly utilized to diagnose semantic pragmatic disorder.

Standardized Assessments: There are a small number of standardized assessments of childhood pragmatic language ability. The Test of Pragmatic Language (Phelps-Terasaki and Phelps-Gunn 1992) and Test of Pragmatic Skills (Shulman 1985) are two of the more widely used assessments, requiring children to formulate appropriate utterances in relation to pictorial and/or verbal prompts. Ability is then compared to age-relevant norms. However, it is been argued that standardized assessments of pragmatic language ability lack true ecological validity for assessing communication in context (Bishop 1998).

Observation in Naturalistic Contexts:

A number of procedures have been developed for the observation and assessment of an individual's pragmatic function in context. These range from a broad assessment, in which a stretch of conversation is rated on several aspects of communicative function (Prutting and Kirchner 1987), to a more fine-grained analysis, which involves coding each utterance in a conversation (Bishop and Adams 1989). Inter-rater reliability for both approaches is known to be high for trained raters. However, this procedure is limited by the often time-consuming process of sample collection, transcription, and analysis. Furthermore, the “snapshot” approach creates uncertainty as to whether the absence of a particular behavior means that this behavior does not occur or whether it occurs rarely but was not observed at the time of sampling.

Ratings: A third assessment method is to obtain ratings of pragmatic language ability from someone who has observed the behavior of the individual over a prolonged period. This approach holds the advantages of being relatively brief and providing a more representative account of an individual's typical ability, including behaviors that occur rarely or are difficult to elicit in test situations. However, ratings are often prone to subjective interpretation, and findings should necessarily be viewed with this in mind. One widely used assessment for evaluating semantic pragmatic disorder is the Children's Communication Checklist (Bishop 1998) and its revised version, the Children's Communication Checklist 2nd edition (Bishop 2003), which have good validity in differentiating between children with specific language impairment, autism, and semantic pragmatic disorder. Adult- (Whitehouse and Bishop 2009) and self-report (Bishop et al. 2009) versions of this checklist have been developed. Other rating scales of pragmatic language include the verbal pragmatic rating scale (Bloom et al. 1999) and the adolescent pragmatics screening scale (Brice 1992). However, these scales do not provide norms and have not been validated for differential diagnoses of semantic pragmatic disorder.

Treatment

Communication difficulties are central to SPD, and thus, the primary intervention strategy is speech-language pathology. Single-case studies have provided the bulk of empirical data in this area, and, while not without the limitations, these studies suggest that speech-language pathology is effective in remediating pragmatic language difficulties, including poor speech prosody, limited communicative intent, verbosity, impaired turn taking, and reduced nonverbal communication. Findings from these studies emphasize the importance of a thorough assessment of communicative strengths and weaknesses and the provision of intervention targeted to the specific areas of need (Adams 2001; Adams et al. 2006; Adams and Lloyd 2007). Findings suggest that intensive therapy (i.e., multiple sessions per week) over a period of at least 8 weeks may provide the most significant benefit. While there is some indication that improvement in pragmatic language following speech-language therapy may endure beyond the period of direct intervention, there have been no long-term follow-up studies.

Sensation Avoiding

Sandra Hodgetts

Pediatrics, University of Alberta, Edmonton, AB, Canada

Synonyms

[Sensory avoiding](#)

Definition

Sensation avoiding is the tendency to avoid sensory stimulation. According to Dunn's Model of Sensory Processing, persons who tend to avoid sensation have a low neurological threshold for sensation (meaning that they notice stimuli very easily), and actively attempt to manage the stimulation (Dunn 2001). Thus, sensation avoiders may be very rigid, ritualistic, and rule-bound in an attempt to control and limit stimulation in the context of daily life and reduce the amount of unpredictable stimulation. Sensation avoiders may also actively

attempt to terminate a sensation, for example, by covering one's ears, leaving a room, or avoiding crowded places. Dunn's conceptualization of sensation avoiding has been supported with standardized measures of people's responses to sensory events in daily life (Infant/Toddler Sensory Profile, Sensory Profile, Adolescent/Adult Sensory Profile), and physiological responsiveness to stimuli. On the Sensory Profile, children with autism spectrum disorders demonstrate patterns of sensation avoiding more than their peers without autism (Ben-Sasson et al. 2009).

Persons with autism who are sensation avoiding have a low tolerance for stimulation. This means that even very-low-intensity levels of sensation may be overwhelming and may interfere with everyday functioning. For example, a sensation avoider may have a negative emotional response to sensory input that someone may not normally find bothersome or even notice. Although sensation avoiding can occur for any and all sensory systems in persons with autism, extreme sensitivities to auditory stimuli are commonly reported based on parental observation and first-hand accounts from persons with autism. For example, many persons with an autism spectrum disorder have reported hypersensitivity to the "buzz" of florescent lights or "whir" of ceiling fans. Selective feeding ("picky eater"), thought to be due to extreme sensitivities to tactile stimuli and texture, is also commonly reported in persons with autism.

Interventions do not typically target changing one's way of processing information. Rather, strategies are used that enable improved performance in daily activities regardless of sensory processing patterns. Strategies to support someone who demonstrates sensation avoiding include creating environments with decreased stimulation, reducing unpredictable stimuli that occur during activities, and respecting one's need for control over their environment, perhaps through routines and rituals.

Sensation-Seeking

Sandra Hodgetts

Pediatrics, University of Alberta, Edmonton, AB, Canada

Synonyms

[Sensory seeking](#)

Definition

Sensation-seeking is the tendency to pursue sensory stimulation and excitement. According to Dunn's Model of Sensory Processing (2001), sensation seekers generally have a high threshold for sensation (meaning that they require a lot of stimuli to notice), and actively seek out stimulation. Thus, sensation seekers can be very active and fidgety, can appear excitable and engaged, and can enjoy a variety of stimuli in their environment. For example, a child who is sensation-seeking might wiggle excessively in his chair at school to provide extra movement, hum, or make other noises to add auditory stimuli to his environment, or be excited and engaged by the variety of decorations, music, and smells of a holiday party. Differences in physiological responses (e.g., heart rate) to new stimuli have been reported in

sensation seekers versus non-sensation seekers in the literature.

Individuals with Autism Spectrum Disorders (ASDs) are often reported to have unusual responses to sensory stimulation, including sensation-seeking behaviors. Persons with autism who are sensation-seeking have a high tolerance for stimulation and derive pleasure from sensation. Thus, they demonstrate a craving for stimulation, and an interest in sensory experiences that are more intense or prolonged than what might be typically expected. Sensation seekers are typically under-responsive to environmental stimuli compared to others; thus, they require increased sensation to maintain an optimal level of arousal to participate in daily activities.

The empirical evidence for sensation-seeking in persons with ASD is mixed. Studies using caregiver questionnaires show lower or similar occurrence of sensation-seeking behaviors in toddlers with autism spectrum disorders compared to typically developing peers. However, older children, youth, and adults with autism tend to experience increased sensation-seeking behaviors compared to typically developing peers. While previous research indicated that sensory processing patterns are relatively stable across the life span, a recent meta-analysis indicated that sensory-seeking behaviors may peak in early to mid-childhood (6–9 years). Also some evidence exists that sensory-seeking behaviors may be more prominent in persons with autism (“autistic disorder”) than in persons with a diagnosis on the broader spectrum (i.e., ► [“Asperger Syndrome”](#), ► [“Pervasive Developmental Disorder Not Otherwise Specified”](#)). Overall, the literature in this area is sparse and is less consistent in sample selection, diagnostic information, and the methods used. There is also a dearth of information on adolescents and adults with autism spectrum disorder.

Interventions do not typically target changing one's way of processing information. Rather, strategies are typically used that enable improved performance in daily activities regardless of sensory processing patterns. Strategies to support someone who demonstrates sensation-seeking include creating environments that provide

increased stimulation. Providing opportunities for increased sensory experiences within the context of everyday activities is important so that the sensation seeker does not have to stop engaging in the activity to obtain the extra sensory input they crave.

Sensitivity and Specificity

Samantha Huestis
Yale Child Study Center, New Haven, CT, USA

Synonyms

[True negative rate](#); [True positive rate](#)

Definition

Sensitivity is the proportion of true positives that are correctly identified by a test or measure (e.g., the percentage of children with autism who are correctly identified as having autism). Sensitivity is calculated by:

True Positives/(True Positives + False Negatives)

*A false negative rate (β) is calculated by $1 - \text{sensitivity}$, or False Negatives/(True Positives + False Negatives)

Specificity is the proportion of true negatives that are correctly identified by a test or measure (e.g., the percentage of children without autism who are correctly identified as not having autism). Specificity is calculated by:

True Negatives/(True Negatives + False Positives)

*A false positive rate (α) is calculated by $1 - \text{specificity}$, or False Positives/(False Positives + True Negatives)

Sensorimotor Development

Suzanne Macari

Yale Child Study Center, New Haven, CT, USA

Historical Background

Arguably the most influential figure in the field of developmental psychology, Jean Piaget authored seminal work on the development of children's intelligence. He posited that cognitive and intellectual changes are the result of development, an active process that the child brings about through interactions with her environment. This process encompasses a series of successive qualitative changes of cognitive structures or schemata created by the child through experience. Piaget's background as a biologist shaped his thinking about the process as a continuous exchange between the individual and the physical world; in other words, "intelligence finds itself entangled in a network of relations between the organism and the environment" (Piaget 1952, p. 19). Piaget's body of work emerged based on extensive, meticulously detailed documentation of his own three children's behavior from birth through adolescence (Piaget 1951, 1952).

The Sensorimotor Stage (Birth to 2 Years)

Piaget (1952) described four stages of cognitive development, the first of which is sensorimotor development. This is the period from birth to approximately 24 months of age that begins with a few reflexes and ends with the appearance of language and symbolic representation of the world. Knowledge in this stage can only be derived from interactions with the physical world, and development proceeds from this exploration. Infants' sensorimotor intelligence proceeds through six increasingly complex stages, each one building on the achievements of the last. In this stage, infants and toddlers do not yet possess the full power of symbolic representation, or language, so must rely on their direct experiences with objects. By around age 2, the child's capacity to represent action in the mind increases, allowing

for conceptual thought, thus lessening the dependence on physical and sensory experience.

Substage I: The Use of Reflexes (0–1 Month)

Infants are born with several reflexes, or general action patterns such as sucking, grasping, and looking. Each reflex constitutes an "organized totality" that includes perceptions, coordinated movements, and a need; it is more than just a "summation of movements" (Piaget 1952, p. 38). These reflexes differ from simple reflexes (i.e., blinking) in that they are modified with experience. At first, there is no differentiation among stimuli; for example, newborn infants will suck on a blanket and on a nipple with equal vigor. After several weeks, infants adjust their sucking to the specific object in their mouth.

Substage II: Primary Circular Reactions (1–4 Months)

When action schemes incorporate new objects, infants move into the second substage of sensorimotor development. In this period, reflexes expand into larger coordinated behaviors, primarily centered on the infants' own bodies. Piaget described systematic thumb sucking and tongue protrusion; looking, hearing, and phonation; and prehension in this substage. Out of the single behaviors of grasping objects and sucking objects grows the integration of these two actions, grasping an object and bringing it to the mouth to suck. The ability to thumb suck at will is one of the *first acquired adaptations* that develops during this period. Turning to find the source of a voice is another primary circular reaction, reflecting coordination between hearing and vision. The term *primary circular reactions* refer to such behaviors. Reactions are primary because they focus on the infants' own bodies, and they are circular because they form "cycles of movements that repeat an interesting sensation discovered by chance" (Muller 2009, p. 208).

Substage III: Secondary Circular Reactions, or the Procedures Destined to Make Interesting Sights Last (4–8 Months)

One of the notable changes in this period is that the child's behavior becomes increasingly

oriented toward the environment, beyond her own body, including people, animals, objects, and events. At this time, infants begin to reproduce interesting actions, such as banging, shaking, and waving, especially when these actions cause an interesting visual effect or sound. “Everything thus goes back to movements of legs or feet, arms or hands, and it is these ‘circular’ movements of prehension which become differentiated in movements directed at shaking, swinging, displacing, rubbing, etc.” (Piaget 1952, p. 178). Infants begin to understand that the interesting events are related to their physical activity and thus reproduce the actions. Another characteristic of this period is the shift toward intentional, goal-directed behavior. During this period, infants still lack the concept of object permanence (see Substage IV).

Substage IV: Coordination of Secondary Schemata (8–12 Months)

Infants begin to use means to attain ends that are not attainable directly. For example, they will push aside a pillow to reach a toy, or pull a string to obtain an object attached to one end. The main achievement of this period is *object permanence*, the awareness that objects exist when they are no longer in sight. During this period, infants begin to search for objects that disappear, indicating that they understand that objects still exist after they disappear from view. The fragility of this mental representation, however, is exemplified in the *A-not-B error*. Once infants have searched for a hidden object at one location (A), when the location is moved (B) they continue to search for it at location A. Not until around the first birthday is the infant able to inhibit search at the previous location and look for the object at the new location.

Substage V: Tertiary Circular Reactions, or the Discovery of New Means Through Active Experimentation (12–18 Months)

Beginning at 12 months of age, infants begin to explore their worlds more actively, “experimenting” with objects, intent on seeing how they behave in new situations. Once making such discoveries, they are repeated, but these

tertiary circular reactions differ from the previous kinds in that the infant varies the actions slightly each time. In this stage, rather than applying the same schemata to problems, they now find new means through trial and error. In contrast to secondary circular reactions, in which infants attempt to recreate a certain event, tertiary circular reactions aim to “ferret out new phenomena” (Piaget 1952, p. 274) in the process.

Substage VI: Invention of New Means Through Mental Combinations (18–24 Months)

In this final stage, the child begins to invent as well as discover. Rather than relying on trial-and-error experimentation, the child begins to be able to devise solutions to simple problems through representation (thinking), independent of immediate experience. In effect, the experimentation happens in thought. This development of mental representation fosters another hallmark of this period, *deferred imitation*, whereby children form mental representations of events so enduring that they can repeat others’ behavior hours or even days after it was first observed.

Current Knowledge

Sensorimotor Development in Autism

Measurement of sensorimotor development in autism was first undertaken in order to assess intellectual functioning in severely affected non-verbal children (Curcio 1978). The Ordinal Scales of Psychological Development had recently been published (Uzgiris 1975) based on Piagetian stages of sensorimotor development in the first 2 years, and was the instrument of choice for many researchers conducting studies in this domain. The resulting studies reported no deficits in children with autism in most areas of sensorimotor development (with the notable exception of gestural imitation) compared to mental-age-matched peers. Furthermore, a relative strength in object permanence skills was often observed in the children with autism (Dawson and McKissick 1984; Morgan et al. 1989; Sigman and Ungerer 1981, 1984; Wetherby and Gaines 1982).

A hypothesis from the literature on typical infant development posited that intentional communication arises in the first year concurrent to the development of Stage IV sensorimotor skills. In other words, the discovery that goals can be met by way of intermediate actions and that other people can act on behalf of the child is necessary before the infant can engage in intentional communication, including actions such as protodeclarative (i.e., showing, pointing to share interest) and protoimperative gestures (i.e., pointing to request) (Bates et al. 1979). Thus, a number of studies were conducted to examine the relationship between sensorimotor skills and communication abilities in children with autism. While some studies found a positive correlation between them (Abrahamsen and Mitchell 1990; Curcio 1978), others reported cognitive skills well beyond the children's language skills (Sigman and Ungerer 1981; Wetherby and Gaines 1982) and thus no clear relationship between the two. Relatively small samples of children of varying ages and ability level as well as different measures of language or prelinguistic functioning may have contributed to the disparate findings.

Sensory Diet

Winifred Schultz-Krohn
Department of Occupational Therapy, San José
State University, San José, CA, USA

Definition

The term “sensory diet” was coined by an occupational therapist, Patricia Wilbarger, following the work of Dr. A. Jean Ayres’ theory of sensory integration. This term refers to the need for an individual to have varied sensory experiences throughout the day, similar to a nutritional diet, to maintain an optimal level of arousal or alertness to meet environmental and task demands.

Historical Background

For well over 40 years occupational therapists providing intervention for children with sensory processing disorders (SPD) or sensory integrative disorders (SID) have advocated for the use of varied sensory experiences to help a child develop more functional and adaptive skills (Ayres 1971, 1973). Characteristically, children who display SPD or SID have very limited variety in their responses to sensory experiences and have difficulties when faced with the need to produce a graded response to a specific situation. Ayres (1973) described a group of children with SID who responded in a defensive manner to seemingly non-noxious or nonirritating sensory

experiences. These children, in particular, seemed to need graded sensory experiences to help them produce functional responses. An example can be seen when a young girl becomes overly distressed to the point of crying when having her hair combed or a boy starts gagging when he smells raw carrots. Children with SPD or SID benefit from varied sensory experiences to help produce a functional and graded adaptive response to a situation. Ayres’ concept of providing graded sensory experiences coupled with child-directed play activities formed the foundation for the concept of a sensory diet.

The term “sensory diet” has been attributed to the occupational therapist Patricia Wilbarger (1984) and then further described by Patricia and her daughter, also an occupational therapist, Julia Wilbarger (1991). They used the term “sensory diet” to describe the use of varied sensory experiences with a graded and child-directed approach to foster organized responses to situations. Following Ayres’ concepts of sensory defensiveness, they postulated that a “sensory diet” would help a “child feel calm, alert, and organized most of the time using special activities” in a manner similar to eating well-balanced meals on a regularly scheduled basis (Wilbarger and Wilbarger 1991, p. 6). These sensory experiences help the child maintain an organized response to functional activities. Although originally applied primarily to children with a sensory defensive profile, the concept of a sensory diet was expanded and used with other children (Williams and Shellenberger 1994) and with adults (Kinnealey et al. 1995).

Rationale or Underlying Theory

For an individual to maintain an optimal level of alertness to effectively respond to environmental situations requires regular and varied sensory experiences or a sensory diet (Wilbarger 1995). The rationale offered includes research addressing deprivation studies and resultant behavioral issues. The concept of a “diet” reflects the need for a variety of sensory experiences and for those experiences to be provided throughout the day in a manner similar to a nutritional diet. The sensory

diet is not the same for each person but instead is tailored to meet the unique needs of the individual (Williams and Shellenberger 1994). Specific areas of the brain respond selectively to various forms of sensory information, but if the brain is deprived of a specific form of sensory information, that portion of the brain will undergo neuroplastic changes to process different information (Merabet and Pascual-Leone 2010). The sensory diet is provided to enrich the brain and foster appropriate processing of sensory information to allow the individual to be alert and adaptive within his or her environment. Individuals who are overly aroused or defensive to a specific form of sensory information often present with maladaptive responses or avoidance.

Goals and Objectives

The goals of a sensory diet follow the overarching goals of sensory integrative therapy, to help the individual produce functional and adaptive responses to the environment (Dunn 2007). To meet this goal, the first concern would be to have the individual achieve and then maintain an optimal level of arousal or alertness needed for the activity (Williams and Shellenberger 1994). From Wilbarger's (1984) concept of a sensory diet, the first sensory systems addressed are proprioceptive, tactile, and vestibular. These follow Ayres' (1972a) classic approach to sensory integrative therapy. The sensory diet includes activities that are designed and structured for the client throughout the day to enhance the level of alertness or arousal needed to meet the functional task. During play activities, the level of alertness or arousal would tend to be higher than during naptime or during meals. The goals are individually developed and reflect a client-centered approach (Pfeiffer et al. 2011; Wilbarger 1995). Instead of prescribing the same sensory experience for every client, the occupational therapist determines what pertinent goals the client or, in the case of very young children and infants, the family wants to achieve. A careful analysis of the individual's

response to current sensory systems and variations in levels of alertness and arousal throughout the day is completed through an interview, and then goals are mutually established. Individuals vary substantially in sensory preferences, and assuming that everyone would benefit from the same sensory experience would be similar to assuming everyone enjoys dark chocolate. Following the interview process, the sensory diet is developed to meet the agreed upon goals. An example can be seen with a child who had difficulties going to bed at night and became very distressed, hyperverbal, and active. Using a weighted blanket to provide deep pressure and then adding slow rocking in a rocking chair helped this child develop the routine of being calm before the event of going to bed instead of viewing this transition as a challenge. The parents had requested occupational therapy services to help with the daily routines related to preparation for going to bed, and the use of the sensory diet was an effective means to meet this specific goal.

Treatment Participants

The sensory diet was initially used for infants and children who presented with a defensive response style to non-noxious sensory experiences (Ayres 1972a; Wilbarger 1984, 1995) but was then extended to children with other SPD or SID profiles (Williams and Shellenberger 1994) and to adults (Kinnealey et al. 1995). The sensory diet has also been used with individuals who are diagnosed with autism spectrum disorders (ASD). The recognition of unusual responses to sensory stimuli for individuals who have ASD has been included in the diagnostic criteria in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR American Psychiatric Association 2000). Evidence of SPD in individuals diagnosed with ASD has been provided by several authors (Barenek 2002; Dunn et al. 2002a; Kern et al. 2006; Kientz and Dunn 1997; Minshew and Hobson 2008; Tomchek and Dunn 2007), and the incidence of SPD for

this population varies from 42% to 88% (Barenek 2002).

Treatment Procedures

The first step is identification of the individual's responses to various sensory experiences and the person's level of alertness or arousal throughout the day. There are reliable instruments available to assist with the identification of sensory responses as similar or dissimilar to peers such as the Sensory Profile (Dunn 1999), Infant/Toddler Sensory Profile (Dunn 2002), Adolescent/Adult Sensory Profile (Brown and Dunn 2002), School Companion Sensory Profile (Dunn 2006), and the Sensory Processing Measure (Miller-Kuhanek et al. 2008). An interview would then identify the patterns of alertness or arousal during the day. The types of task during that portion of the day would be compared to the typical level of arousal needed to meet the task demands and to assess the fit of these factors (Nackley 2001; Wilbarger 1995). For example, a child who is very active and disorganized at the beginning of the school day would have difficulties with the social expectations of sharing toys or playing an interactive game with peers. This child may need additional sensory experiences to help his level of arousal to slightly diminish to a more appropriate level to allow social participation with peers. Information about the individual's ability to transition between various activities should be included in the interview process (Wilbarger 1995).

The second step in the treatment procedures is identification of beneficial sensory experiences that either increase or decrease the level of arousal for the individual as needed to meet task demands (Wilbarger 1995; Williams and Shellenberger 1994). These sensory experiences can be grouped into large categories of sensory input, but the form of the sensory experience may be different for each individual. The three general categories of sensory experiences used in the sensory diet are deep pressure (proprioceptive), movement

(vestibular), and touch (tactile). The sensations of vision, sound, taste, and smell are also used when creating a sensory diet with careful consideration for individual differences. This concept is illustrated with the sense of smell and how a specific odor may be very calming for one individual but distressing to another individual. When looking at the form of the sensory input, it is important to consider the use of this sensory input within the individual's daily life (Nackley 2001). For example, deep pressure (proprioceptive input) may be helpful in modifying the level of alertness to allow individuals to meet task demands, but the form of the deep pressure is often different. For an individual, it is best provided through the use of a weighted vest that is snugly fitted (VandenBerg 2001). Another individual, who also finds the use of proprioceptive input helpful, prefers the use of squeezing a resistive squeeze ball throughout the day to assist with level of alertness (Nackley 2001).

The third step in developing the sensory diet is developing a plan where the preferred sensory experiences can be provided throughout the day (Nackley 2001; Wilbarger 1995). These have been referred to as a "sensory tune-up" and reflect the need to provide the individual with opportunities throughout the day to use sensory input to adjust the level of alertness in preparation for the task demands. Wilbarger (1995) discussed the need to use preferred sensory input prior to transitions between activities in addition to regularly scheduled periods. Specific forms of sensory experiences tend to have longer lasting impact on the level of arousal or alertness. Vestibular-based activities that are alerting, spinning in a revolving chair or on a scooter board, can have effects lasting several hours, and this form of sensory input should only be used following recommendations of a trained occupational therapist. Proprioceptive input can also produced longer lasting results of 1–2 h in duration. Changes in noise and lighting can produce an immediate response in the level of alertness, but the duration tends to be shorter. Wilbarger (1995) notes the visual and auditory sensory

input can also evoke emotional responses and that should be considered when completing the interview process. Nackley (2001) provided a description of how the sensory diet could be structured throughout the school day and coupled with daily tasks.

Efficacy Information

Large randomized controlled trials using a sensory diet have not been completed. The current research addresses use of sensory integration treatment from which a sensory diet was derived. Although numerous studies exist using sensory integration strategies to produce changes, the results have been mixed (May-Benson and Koomar 2010). Often the heterogeneity and small numbers of participants resulted in potential type II errors, and the use of inappropriate measures did not reflect the foundation of sensory integration and the use of a sensory diet, that being an individually designed intervention to help the person respond adaptively and appropriately to task and environmental demands. Recent literature using Goal Attainment Scaling (GAS) as an outcome measure has demonstrated significant improvements when using sensory integration treatment (Mailloux et al. 2007; Pfeiffer et al. 2011). Goal Attainment Scaling (GAS) is a method to foster client participation in the goal setting process that is meaningful and relevant (Pfeiffer et al.). In an investigation comparing the use of sensory integration services to fine motor intervention services for children with ASD, superior gains were reported by parents on GAS scores for those children receiving sensory integration services. Additionally, gains were identified in reduced autistic mannerisms, as measured by the Social Responsiveness Scale for the children receiving sensory integration treatment.

When a sensory diet has been used in conjunction with other sensory strategies, positive results were reported (Hall and Case-Smith 2007). A small study of 10 school-aged children with SPD using a combination of a sensory diet with a therapeutic listening program produced

significant gains in sensory processing scores and handwriting skills.

Outcome Measurement

Recent literature has provided a clearer direction for research on the efficacy of sensory integration treatment of which the sensory diet is derived (Parham et al. 2011). The fidelity measure for Ayres Sensory Integration intervention was developed to insure that therapeutic methods used in an investigation accurately represent the philosophy and principles of this approach. The sensory integration approach described by Ayres (1969, 1971, 1972a, b, 1973, 1982) served as the foundation for the sensory diet (Wilbarger 1984). This fidelity measure identified the need to engage in collaborative goal setting with family members and teachers along with discussing the influence of sensory integration on the individual's participation in functional activities. The use of GAS has shown promise in supporting the principles outlined by Ayres and the fidelity measure. Investigations using GAS have reported improvements following sensory integration (Pfeiffer et al. 2011; Schaaf and Nightlinger 2007).

Qualifications of Treatment Providers

The fidelity measure of Ayres Sensory Integration intervention stipulates that the therapist receive post-professional training in sensory integration with a minimum of 50 educational hours in theory and practice. The sensory diet was developed from the theory of sensory integration, and these standards should be applied. Occupational therapists are the professionals most frequently pursuing advanced training in the theory and practice of sensory integration beyond the post-professional basis. The entry-level occupational therapist has completed courses within the professional preparation to understand the neuroanatomy, neurophysiology, and occupation base of sensory integration theory and practice.

SEQ

Description

The Sensory Experiences Questionnaire (Version 3.0; SEQ; Baranek 2009; Ausderau et al. 2014b) is a caregiver report assessment intended to be used by researchers and clinicians to characterize the sensory features in children ages 2–12 years with autism spectrum disorder (ASD) and/or other developmental disabilities (DD). The questionnaire typically requires about 15–20 minutes for a parent or caregiver to complete. If needed, the SEQ (Version 3.0) can also be administered in a structured interview format. The SEQ (Version 3.0) has 105 items that measure the frequency of

sensory features across four sensory response patterns (i.e., Hyporesponsiveness; Hyperresponsiveness; Sensory Interests, Repetitions and Seeking behaviors (SIRS), and Enhanced Perception), which reflect items across five sensory modality categories (i.e., auditory; visual; tactile; gustatory/olfactory; and vestibular/proprioceptive), and across two contexts (i.e., social or non-social). The first 97 items measure the frequency of the child's sensory behaviors using a 5-point Likert scale ranging from 1 (almost never) to 5 (almost always). The last eight items ask broader questions about the child's sensory experiences and allow the caregiver to elaborate with a qualitative response. The summary scores for the four sensory response patterns are calculated based on the 97 quantitative items, excluding control items, with the qualitative answers providing further contextual information. A higher score indicates a greater frequency or intensity of sensory features.

Historical Background

The Sensory Experiences Questionnaire, formerly known as the Sensory Supplement Questionnaire (SSQ), was developed by Grace Baranek in 1999. It has been through four revisions (Versions 1.0, 2.0, 2.1, and 3.0) to better meet research needs and the evolving conceptual model. The revisions have included refining items for a broader age range, expanding the number of items, adding control items, increasing the types of sensory patterns represented, and further psychometric studies. The items included in the SEQ (Version 3.0) were developed from a review of existing literature on sensory features in children with ASD including empirical studies (Ayres and Tickle 1980; Baranek et al. 1997, 2005, 2014; Ben-Sasson et al. 2009; Dahlgren and Gillberg 1989; Iarocci and McDonald 2006; Lord et al. 1994; Rogers and Ozonoff 2005; Stone and Hogan 1993), parental report studies (Kientz and Dunn 1997; Lord 1995; Ornitz et al. 1977; Rogers et al. 2003; Stone and Hogan 1993), expert clinical reports (Greenspan and Wieder 1997), conceptual models of sensory processing (Ayres 1989;

Baranek et al. 2001; Dunn 1997; Miller et al. 2001), and consideration of neuropsychological theories of ASD describing core features (Mundy and Neal 2001; Ozonoff et al. 2005; Rajendran and Mitchell 2007; Volkmar et al. 2004; Waterhouse et al. 1996).

Psychometric Data

Throughout the development of the SEQ, the psychometric properties of the versions have been assessed on an ongoing basis to ensure its reliability and validity. The overall internal consistency of the SEQ (Version 1.0) (21-item version) was 0.80 (Cronbach's alpha) (Baranek et al. 2006) and the test-retest reliability was 0.92 (intraclass correlation coefficient) (Little et al. 2011). Reliability analysis (internal consistency) of the subscales for the SEQ (Version 2.1) yielded the following psychometrics (Cronbach's alpha): Hyperresponsiveness = 0.73; Hyporesponsiveness = 0.75; Sensory Seeking = 0.80; Social = 0.69; Nonsocial = 0.78 (Little et al. 2011).

A known-groups validity study with 258 caregivers of children ages 5–80 months found that the SEQ (Version 1.0) discriminated well between children with ASD and those with other DD, as well as those with typical development (Baranek et al. 2006). Prevalence of overall sensory features for the ASD group was 69% (versus 38% for the DD group) based on the items sampled. Sensory symptoms were inversely related to mental age such that more developmentally mature children across the groups demonstrated fewer sensory features. Children with ASD in this study had increased levels of overall sensory features as well as increased patterns of Hyporesponsiveness compared to children with other DD in both social and nonsocial contexts. Children in any of the clinical groups (those with ASD as well as those with DD) showed increased levels of Hyperresponsiveness compared to typically developing children. This study demonstrated the SEQ's ability to discriminate unique pan-modal sensory response patterns in children with ASD from comparison groups.

Walz and Baranek (2006) using the SEQ (Version 1.0) demonstrated the SEQ's validity for characterizing sensory response patterns in children with Angelman syndrome through 18 years of age. In a longitudinal analysis of sensory processing, Baranek et al. (2008) demonstrated that the SEQ (Version 1.0) was sensitive to maturational changes when examining developmental trajectories of sensory processing in 13 boys with fragile X syndrome from ages 9 months through 5 years.

Two studies showed the utility of the SEQ to predict to restricted and repetitive behaviors (RRB). Boyd et al. (2010) used the SEQ (Version 2.1) in combination with other sensory measures to examine the association between three sensory response patterns and RRB in children with ASD ($n = 67$, mean age = 51.69 months) and DD ($n = 42$, mean age = 49.45 months). The sensory measures used in this study included the SEQ and were used to validate three sensory constructs (i.e., Hyporesponsiveness; Hyperresponsiveness; and Sensory Seeking) through a factor analysis. Model fit was assessed using standard fit measures: Chi-square = 32.4 (31), RMSEA = 0.021, and CFI = 0.997. A major finding of the study was the significant association between Hyperresponsiveness and the presence of RRB in children with ASD and DD and primarily nonsignificant associations with the other sensory response patterns. A more recent study with 87 toddlers at elevated risk for ASD showed that the SEQ (Version 2.1) Hyperresponsiveness predicted significantly to later RRB symptoms at 3–5 years of age (Grzadzinski et al. 2020).

To further assess the relationship between the sensory response patterns (i.e., Hyporesponsiveness; Hyperresponsiveness, and Sensory Seeking) and social communication in children with ASD ($n = 72$, mean age = 52.3 months) and DD ($n = 44$, mean age = 48.1 months), Watson et al. (2011) used the SEQ (Version 2.1) in combination with other sensory measures to determine children's sensory response pattern scores and other measures of social-communicative symptoms of ASD, as well as language, social, and communication skills. A primary finding of the study was a

positive association between Hyporesponsiveness and social-communicative symptom severity for both the ASD and the DD groups. Hyperresponsiveness was not associated with social-communicative symptom severity for either groups, and Sensory Seeking was only associated with social-communicative symptom severity in the ASD group. The SEQ (Version 2.1) was able to be used in combination with sensory measures to assess their unique association with social communication as well as other language and communication skill measures.

Using a national sample of 1,307 children with ASD, Ausderau et al. (2014) empirically validated the factor structure the SEQ (Version 3.0). A confirmatory factor analytic model with 10 latent variables: four substantive factors of hypothesized sensory response patterns (i.e., Hyporesponsiveness; Hyperresponsiveness; SIRS; and Enhanced Perception), five method factors of sensory modalities (i.e., auditory, visual, tactile, gustatory/olfactory, and vestibular/proprioception), and one social context were tested, resulting in good model fit.

Correlations between the substantive factors were freed, but fixed to zero between the method factors, as well as between the method factors and the substantive factors. Model fit for this confirmatory factor model was assessed using standard fit measures: Chi-square = 16,724.18 (3984) ($p < 0.01$), RMSEA = 0.051, and SRMR = 0.07. Factor loadings for the items on the latent variables were generally strong and provided support for each of the hypothesized sensory content factors. Between-factor correlations ranged from 0.44 to, suggesting that these factors were distinct and they covaried significantly. The study confirmed the factor structure for the SEQ (Version 3.0), and tested measurement invariance for age and sex. To understand the impact of the four sensory response patterns on autism severity, this study also conducted a mixed model regression analysis, controlling for key child (i.e., chronological age, IQ, sex) and family characteristics (e.g., education and income). All four sensory response patterns

significantly predicted autism severity as measured by the Social Responsiveness Scale (SRS).

Two subsequent large sample studies demonstrated the utility of the SEQ (Version 3.0) for subtyping ASD sensory features. One study with 1294 children with ASD found four sensory subgroups of children with ASD (i.e., Mild; Attenuated-Preoccupied; Sensitive-Distressed; and Extreme) (Ausderau et al. 2014a) and these subtypes were found to be highly stable over a 1-year period based on a latent profile transition analysis. In addition, a follow-up study (Ausderau et al. 2016) found that the four subtypes measured by the SEQ (Version 3.0) were found to predict differentially to outcomes in adaptive behavior, parenting stress, and autism severity 1 year later in a sample of 884 children with ASD.

Baranek et al. (2019) conducted a study to look at the stability of sensory features in a longitudinal study with 55 children with ASD and 35 with DD. Regression analyses revealed that for both groups SEQ (versions 2.1 and 3.0) sensory response pattern scores early in development (preschool period) were significantly strong predictors of scores 3 years later (on average). Correlation coefficients between the two time points were statistically significant (Hyporesponsiveness 0.63–0.64; Hyperresponsiveness 0.55–0.60; SIRS 0.63–0.73) for the two groups. Mean scores were found to decline for SIRS in both groups and for Hyporesponsiveness in the ASD group. Therapeutic services received between the two time points were positively associated with the severity of sensory features, suggesting that children with more severe sensory processing problems may fail to improve over time.

Clinical Uses

The SEQ is meant to be used alone or in combination with other diagnostic tools by researchers and clinicians. It can be used to characterize sensory features in children by sensory response pattern, modality, and social context. The SEQ can also be used to assist in discrimination of sensory

features that are specific to children with ASD versus those with DD or typical development. Clinicians can identify and quantify the frequency of a range of sensory features in children that may require further evaluation and/or intervention. The characterization of the sensory features or sensory subtypes may also assist clinicians in treatment planning. Information gleaned from the SEQ (Version 3.0) can be used to develop targeted, personalized interventions. Clinicians interested in using a strengths-based approach to working with children with ASD may find the SEQ (Version 3.0) particularly relevant, as the Enhanced Perception construct may enable clinicians to address an area of particular strength in some individuals. The SEQ is a reliable and valid tool that may be useful in monitoring changes in sensory features over time as a result of maturation or intervention.

The SEQ can be used by researchers to screen for inclusion into certain research studies, to characterize sensory features in children with ASD or DD, and to assess the stability or change in sensory features over time as related to sensory response pattern, modality, and context. It also provides an assessment tool to relate sensory features of children to a variety of outcome variables such as children's autism severity, adaptive skills, or parenting stress. The SEQ (Version 2.1) has been used in at least two randomized controlled trials (Baranek et al. 2015; Watson et al. 2017).

multisensory integration and sensorimotor functions such as motor planning (Brandwein et al. 2013; Foxe et al. 2013; Russo et al. 2010). Parents of children with ASD report that these sensory features are among the most challenging that they face in managing their children's behavior and their daily life (Schaaf et al. 2011). Parents rate intervention for sensory difficulties as one of their top priorities and most helpful interventions (Myers et al. 2009; Peacock 2012). Studies show that up to 95% of children with ASD exhibit these sensory features (Baker et al. 2008; Ben-Sasson et al. 2009) and that sensory features may help differentiate ASD from children with other clinical disorders (Baranek et al. 2006).

Despite the prevalence of sensory features in ASD and their potential impact on function and behavior, there is a lack of consensus regarding the value of sensory features in the autism phenotype. Some argue that sensory features have important diagnostic value, whereas others suggest that they are not a distinguishing characteristic and thus should not be included in the DSM-5 as a diagnostic characteristic. This chapter will explore sensory features in ASD with a focus on their value as a core phenotypic marker of ASD.

Sensory Features as a Marker of Autism Spectrum Disorders

Roseann Schaaf

Farber Institute for Neurosciences, Jefferson
College of Rehabilitation Sciences, Thomas
Jefferson University, Philadelphia, PA, USA

Definition

Sensory features are included as one of the diagnostic markers of autism spectrum disorder (ASD) under the restrictive and repetitive behaviors, interests, or activities diagnostic criteria in the DSM-5 (American Psychiatric Association [APA] 2013). Sensory features are defined as hypo- and hyper-reactivity to sensation and unusual interests in sensory aspects of the environment in the DSM-5 but have also been shown to include difficulties with

Historical Background

Sensory features were first noted as part of the autism phenotype by Kanner in 1943. Later, Wing (1969) argued that sensory abnormalities are an underlying impairment in autism. Thus, in the early years of autism, sensory features were considered a key aspect of the autism phenotype. However, as more studies were conducted on the cognitive and social aspects of autism, a more social cognition view of autism became predominant in the field (e.g., Rutter 1983). This view purported that cognition and language impairments are the core features of ASD and sensory symptoms were viewed as by-products of primary deficits in social cognition. Based on this perspective, sensory features were subsequently removed from the DSM as a key diagnostic marker of ASD. Over the subsequent years, the key role of sensory

features in ASD has been debated. In 2013, findings related to the prevalence and ubiquitous nature of sensory features in ASD resulted in sensory features again appearing in the DSM-5 (APA 2013). Sensory features are now a component of the ASD diagnostic criteria in the DSM-5 under the restricted and repetitive behaviors' diagnostic marker. They are included as one of the four potential markers of the restrictive and repetitive behaviors, interests, or activities diagnostic criteria as shown below:

Restricted and repetitive patterns of behaviors, interests, or activities as manifested by at least two of the four symptoms (APA 2013):

- Stereotyped or repetitive speech, motor movements, or use of objects
- Excessive adherence to routines, ritualized patterns of verbal or nonverbal behavior, or excessive resistance to change
- Highly restricted, fixated interests that are abnormal in intensity or focus
- **Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment**

Current Knowledge

Sensory Features as a Diagnostic Marker of ASD

As stated above, there is a continued debate about whether sensory features are a distinguishing diagnostic feature of ASD. In support of their value as a diagnostic marker, Robertson and Baron-Cohen (2017) find strong evidence that sensory symptoms are a “core, primary characteristic of the neurobiology of autism, and that sensory differences are a core phenotypic marker of ASD” (p. 674). They base this conclusion on the evidence that sensory symptoms are present early in development (as early as 6 months of age), are predictive of later diagnostic status, affect every sensory modality, and are estimated to occur in as many as 90% of autistic individuals (as cited in Robertson and Baron-Cohen 2017). Genetic and neuroimaging studies (summarized below) also provide additional evidence of the unique contribution of sensory features to the autism phenotype.

Genetic evidence suggests that there is some genetic heritability of sensory features in ASD with greater sensory symptoms in families that are believed to have a higher genetic inclination for autism (multiplex families) than in families with a single individual diagnosed with autism (simplex families). Further, there is some evidence showing that parents and siblings of individuals with ASD show higher levels of self-reported sensory traits relative to the general population (Donaldson et al. 2017). Research showing that sensory features may distinguish those with ASD from other genetically based neurodevelopmental conditions supports this position. For example, Bizzell et al. (2019) found that sensory features differentiate ASD from other clinical disorders in a genetically homogeneous group of boys with 46,XXX syndrome. Thirty percent of these boys with XXX meet the criteria for ASD, and those with XXX + ASD showed sensory features comparable to boys with ASD. This finding suggests that sensory features may be a distinguishing characteristic for the ASD phenotype. Further, Robertson and Baron-Cohen (2017) suggest that data showing that sensory patterns in neurodevelopmental disorders such as Rhetts syndrome and dyslexia are distinctly different than those with ASD support the view that sensory features may serve as a “selective, objective marker of autism” (p. 676).

Further supporting the view that sensory features are a key distinguishing characteristic of ASD is neurological evidence. For example, imaging studies show alterations in sensory-dedicated neural circuitry at the molecular and anatomical levels in primary sensory regions of the brain associated with sensory features in autism and that these findings are primary rather than secondary consequences of alterations in higher-order cognitive processes. Robertson and Baron-Cohen (2017) summarize these findings and conclude that the pattern of findings, regarding atypical sensory responses in primary sensory cortices as well as the alterations in the functional architecture of sensory cortex, is compatible with the hypothesis that sensory differences are a core phenotypic marker of autism. Another key finding here is that there is disruption in the excitatory-

inhibitory balance in the brain of individuals with ASD that may lead to differences in the perception and processing of sensory information and that difference in GABA may mediate these differences (Robertson and Baron-Cohen 2017).

In contrast, some researchers suggest that sensory features are not a phenotypic characteristic of ASD. For example, Grapel et al. (2015) found that adolescents and adults with ASD (including PDD) did not show differences in parent-reported sensory-related issues in comparison to others with developmental or behavioral difficulties (not ASD). They question the rationale for including them as a diagnostic criterion for ASD: While sensory symptoms are “relatively common in ASD, they do not discriminate autism nearly as strongly as the core social dysfunction and they are frequent in other developmental problems” (p. 71). They conclude that sensory features are not a marker of ASD and question the rationale for including them as a diagnostic criterion for ASD. In support of this view, McCormick et al. (2016) conducted a longitudinal study comparing sensory symptoms in ASD, developmental delay, and typically developing children ages 2–8 ($n = 79$) at three time points and found that there were not significant differences in sensory symptoms between the two clinical groups (ASD and DD). This finding supports the notion that sensory symptoms are not a diagnostic feature of ASD. One confound to this study is that they used the Short Sensory Profile (McIntosh et al. 1999) to evaluate sensory features which is biased toward reporting hyper-reactivity over other types of sensory features.

Although this evidence is persuasive, it is confounded by age, autism severity, and assessment strategies used to identify sensory features. Regarding age, given that there is evidence that sensory features are stable through the preschool years (from ages 3 to 6) but then tend to decrease with age, the age range included in a given study will impact findings. Further, severity of autism tends to impact sensory symptoms, whereby the greater severity of ASD is associated with great sensory features (Leekam et al. 2007). Another confound to these findings is that terminology patterns have varied across studies and, over the years, as have assessments used to identify

sensory features making it challenging to compare findings. Finally, few longitudinal studies have tracked sensory features in ASD over time which further limits the ability to interpret the data and make strong conclusions about the role of sensory features in the autism phenotype.

Early Sensory Symptoms Impact the Neurodevelopmental Trajectory

Regardless of their unique contribution to the autism phenotype, it is clear that sensory features impact future development. One promising area of research is the idea that early, atypical sensory processing and integration has cascading effects on social, communicative, and emotional development (Hannant et al. 2016). Studies suggest that low-level sensory-perceptual alterations (i.e., perception of sensory cues) may lead to downstream effects such as altered neural connectivity that impact higher-level deficits in cognition, language, praxis, and socialization in individuals with ASD (Cascio et al. 2016). A central tenet of this line of investigation is that early atypical sensory perceptions and experiences set the stage for an abnormal neurodevelopmental trajectory that further affects development and elaboration of functional brain networks that are key in autism symptomatology. Future work in this area will likely provide insight into the unique contributions of early sensory processing, perception, and integration on the autism neurodevelopmental trajectory and subsequently on the expression of autism behaviors.

Relationship of Sensory Features to Autism Severity and Other Symptoms

Additional evidence for the impact of sensory features in ASD comes from data showing that sensory features influence other ASD behaviors. Sensory features are shown to predict deficits in social and cognitive function and explain independent variance in social and communication symptoms in diagnostic assessments (Frazier et al. 2012; Turner-Brown et al. 2013). Further, sensory features are predictive of social deficits and repetitive behaviors (Boyd et al. 2010) as well as eventual diagnostic status (Donaldson et al. 2017). Large-scale studies demonstrate covariance between questionnaire-based measures of

sensory sensitivities and autistic traits (see, e.g., Mayer (2017)). These correlations present a strong argument for a relationship between sensory and social-cognitive processing in autism.

Further, sensory symptoms are associated with decreased participation in daily living and leisure activities for children with ASD and their families (Schaaf et al. 2011) as well as caregiver strain (Kirby et al. 2019). Dunn et al. (2016) conducted a scoping review to examine the impact of sensory features on daily living in children. They found a link between sensory processing (measured by a variety of sensory measures) and participation in many areas including daily living skills, play/leisure activities, and social participation. Although this study was not specific to ASD, it shows the potential impact of sensory features on daily lives. Similarly, Jasmin et al. (2009) found high correlations between sensorimotor deficits and daily living skills in ASD.

To explore the impact of intervention designed to address sensory features on daily life function and participation in children with ASD, Schaaf et al. (2014) conducted an intervention study designed to assess the impact of occupational therapy intervention using Ayres Sensory Integration[®] on functional skills. They found that Ayres Sensory Integration[®] intervention improved function and participation in children with ASD in those who received the intervention in comparison to those who continued treatment as usual (Schaaf et al. 2014). This study provided the first solid evidence that an intervention targeting sensory features had a value for improving function and participation in children with ASD and resulted in Ayres Sensory Integration[®] meeting the criteria for an evidence-based intervention for ASD (Schoen et al. 2019). Currently, Molholm, Schaaf, Foxe, and colleagues are conducting a large, NIH-funded comparative effectiveness trial comparing ASI and behavioral intervention/discrete trial training on functional skills (1R01HD082814-01A1). This trial is underway and will provide further insight into the value of interventions that target sensory features and their impact on function and participation. Further, this study will evaluate the impact of the interventions on sensory features directly,

including neural and behavioral markers, an area that has not been investigated but that is needed.

Sensory Subtypes in ASD

Given that sensory features in ASD are heterogeneous and ubiquitous, the identification of specific subtypes of sensory features in ASD holds a promise for reducing heterogeneity and for guiding future research and tailoring interventions. However, it is likely that subtypes of sensory features will vary by person, by age, and by severity of autism. However, to date, researchers have not found a consistent set of subtypes of sensory features that are universal to ASD. Rather the data show that sensory features are heterogeneous. The interpretation of this literature is complicated by variations in terminology, differences in operational definitions of sensory features, differences in assessment measures used to classify sensory features, variability in the statistical procedures used to subtype data (e.g., latent class analysis, factor analysis, cluster analysis), as well as the age group of the sample. Common patterns identified include hypo-reactivity (decreased or delayed response to sensory inputs); hyper-reactivity (exaggerated response to sensory stimuli); and sensory seeking behaviors, also termed extreme sensory interests or repetitive sensory behaviors (fascination with or physically active behaviors to obtain sensory input) (APA 2013). Subgroups of sensory features also include enhanced perception (superior sensory acuity)/decreased sensory perception (lack of sensory acuity); mild to severe sensory features (Ausderau et al. 2014); hypo-, hyper-, and multisensory patterns (Lane et al. 2014); and uniformly elevated sensory symptoms or raised sensory avoiding and sensitivity using the Short Sensory Profile-2 (Simpson et al. 2019). Thus, the subtyping effort has not yielded specific universally accepted patterns, but rather an acceptance that sensory features are heterogeneous and that further efforts to identify subtypes may be useful to tailor interventions more specifically to the sensory needs of each individual and to guide future research into the sensory features of ASD.

Studies of Specific Sensory Modalities in ASD

Researchers have found sensory differences in many sensory systems in ASD, as well as

differences in multisensory integration. Findings point to both reduced and enhanced perception and reactivity, with personal accounts often differing from physiological or neurological findings. For example, studies of auditory processing have shown reduced temporal processing and delayed responses (Kwakye et al. 2011), whereas first-person accounts often report heightened sensitivity and avoidance responses (Grandin and Panek 2013). Studies of tactile processing have shown both superior (Blakemore et al. 2006) and reduced (Puts et al. 2014; Tavassoli et al. 2016; Marco et al. 2012) tactile threshold detection (see Mikkelsen et al. (2018) for a review). However, more recent evidence from Puts' lab is showing that tactile reactivity may be related to an attentional issue rather than autism. They showed that children with ASD have normal reaction times to tactile stimuli but that children with ASD + ADHD and ADHD only have slower reaction times (unpublished data). This finding suggests that ADHD may be the confounding factor regarding tactile detection thresholds in ASD. Further, Puts' team is showing evidence of abnormal sensory gating in ASD suggesting impaired feedforward inhibition such that children with ASD do not show the typical suppression (gating) of tactile stimuli following subthreshold stimuli (Puts et al. 2017). These findings show a promise in terms of understanding the mechanisms of sensory features in ASD and furthering our understanding of the unique aspects of sensory features in ASD.

In the area of proprioception, Mostofsky and Ewen (2011) show evidence of enhanced reliance on proprioceptive cues for movement in motor learning tasks, while Smith-Roley et al. (2015) showed signs of reduced proprioceptive perception in behavioral tasks designed to measure proprioceptive awareness, perception, and accuracy.

Visual processing and perception in ASD is characterized by strength in detail focused visual percept and difficulty with global percept (Robertson and Baron-Cohen 2017). Further, there appears to be faster detection of single visual targets in a cluttered visual display among distractors; greater detection or discrimination thresholds for static stimuli with deficits in visual motion processing (ability to identify global

direction of a visual signal). These deficits in visual motion are predictive of severity of autism symptoms.

To test the hypothesis that differences in visual perception and processing in ASD are related to lack of excitation/inhibition balance, Robertson conducted binocular rivalry experiments. Binocular rivalry is a "basic visual function [experiment] that depends on the strength of inhibitory interactions in the visual cortex" (Robertson and Baron-Cohen 2017, p. 676). Binocular rivalry tests the brain's ability to suppress alternating back and forth perception in each eye in the visual cortex. They found that persons with ASD show reduced strength of perceptual suppression and this deficit is associated with reduced GABAergic action in early visual cortex.

Pain – There have been reports of both hypo- and hyperresponses to pain in ASD (Grandin and Panek 2013; Yasuda et al. 2016). Failla et al. (2018) found an intact early response to pain in adults with ASD with a reduction in response as the stimulation continued. They suggest that alterations in pain perception reported by individuals with ASD may be due to altered coping strategies or top-down modulation of sustained pain; however, this hypothesis needs to be further studied and validated and points to the need to study both immediate and sustained reactions of pain but also of all sensory modalities.

In summary, the data on single sensory modalities processing in ASD has not reached consensus although there appears to be an emerging theme of lack of inhibition or modulation/gating of sensory input in ASD that underlies hyper-reactivity to sensation in the tactile and visual systems. Further, there is some evidence that reduced GABA may be the mechanism underlying hyper-reactivity, but more research is needed to confirm this hypothesis. There is very little research on sensory perception in ASD as there appears to be a tendency to study sensory reactivity over perception, and more research is needed in the area of perception and discrimination of sensation in ASD. The nature and extent of sensory features in ASD has proven to be a challenging area of research that requires more attention and focus in ASD (Grandin and Panek 2013).

Multisensory Integration

There is evidence that multisensory integration, the ability to perceptually bind two or more sensory inputs in time and space, is altered in ASD. Studies show that the temporal binding of two concurrent sensations from different sensory modalities (i.e., auditory and visual or visual and somatosensory) is slower with an elongated temporal binding window (Stevenson et al. 2016; Wallace and Stevenson 2014; Brandwein et al. 2013). This delay in temporal binding impacts the ability to integrate sensory stimuli in “real” time. Functionally, this lack of multisensory integration may manifest as decreased or slow to respond to multisensory inputs. Given that most activities in the everyday world require multisensory integration, it is easy to imagine the impact that decreased multisensory integration would have on function and behavior. Responses may be slow, absent, or unusual. Delay in multisensory integration is a highly replicated finding, and it has been associated with autism severity (Brandwein et al. 2013). However, its ability to distinguish autism from other clinical disorders has not been established.

Future Directions

Further research is needed to fully understand sensory features in ASD and their contribution to the autism phenotype. Research should extend beyond sensory reactivity (hypo-hyper) to include sensory perception and integration. Research extending the concepts of detail versus global perception, central coherence, and immediate versus sustained responses is needed across all sensory systems. Further exploration of sensory gating across sensory systems will also shed light on the potential mechanisms of hypo- and hyper-reactivity in ASD and the potential role of GABA in sensory reactivity. Further, to allow for comparison of studies across study sites and protocol, a specific assessment protocol that has universal acceptability and that combine performance-based and proxy report (Schaaf and Lane 2015) will improve our understanding of sensory features in ASD and allow for more

accurate subtyping to reduce heterogeneity and improve precision in research and practice.

Sensory History

Kristen M. Powers

Coordinator of Rehabilitative Services, Center for Children with Special Needs, Glastonbury, CT, USA

Definition

As part of a comprehensive occupational therapy evaluation for a child with underlying sensory processing challenges, the examiner may perform standardized assessments to evaluate motor performance and motor planning abilities. Using such instruments at the SIPT (Sensory Integration and Praxis Tests), the examiner will be able to identify additional deficits in sensory processing.

The examiner will also obtain a sensory history with the caregivers or client to evaluate the impact of sensory processing deficits on activities of daily living, leisure skills, and social interactions. This will allow the examiner to more fully understand sensory processing abilities and behavioral consequences to proceed with an intervention plan appropriate to the individual.

Sensory Impairment in Autism

Rita Jordan
School of Education, University of Birmingham,
Edgbaston, Birmingham, UK

Definition

Sensory impairments are used in two ways in the context of autism. They may indicate a dual

disability of autism plus a sensory impairment as, for example, autism and visual impairment, autism and hearing loss, or autism and a sensory-motor impairment. There is nothing in the etiology of autism that protects against comorbidities, and clearly the sensory impairment will interact with the autism to produce a person-specific range of difficulties and a particular developmental path. Individuals with dual or even multiple diagnoses of this kind will not only have more difficulties to overcome but may have fewer compensatory strategies available to them. In addition, it will be harder to find appropriate support in education, social care, and vocational training, where key staff need to be knowledgeable about autism as well as the sensory impairment.

However, a separate sensory disorder is fairly uncommon in autism. The term “sensory impairment” is more commonly used to apply to sensory issues that many believe are central to autism itself. These are sensory processing problems, which are not severe enough to reach criteria as a separate sensory disorder. Sensory processing disorder (SPD) is currently still not accepted as a separate diagnostic category in its own right in DSM V (APA 2013) so it still cannot be considered as a co-morbidity in autism. Nevertheless, associated sensory features were accepted as part of the autism diagnosis in DSM-V with two broad characterizations of ‘sensory seeking’ (sensory under-responsivity) versus ‘sensory avoiding’ (sensory over-responsivity) being used as part of the characterization of the child at diagnosis. Sensory processing differences have been identified with autism since it was first categorized, but they have never before featured in the diagnostic criteria. Although there has been growing research interest in this issue, and the recognition of the key role sensory processing problems may have in autism (Baker et al. 2008), it had been the consensus that sensory problems were neither universal in, nor unique to, autism.

All forms of sensory input processing have been suggested as being impaired in autism, although only a limited range of senses has been studied. The nature of the difficulties has been defined as hyposensitivity or hypersensitivity in particular sensory domains although there are also

said to be issues with the latency and timing of responses to sensory input. The most studied have been auditory and visual processing, although some research suggests the proximal senses (touch, taste, smell) and motor senses are most affected in autism. There has also been considerable debate about the existence of a problem with multisensory integration in autism. Pain is a sense, the processing of which is also said to be disturbed in autism, and clearly this is very important in development and learning. However, there has been little research and some equivocal results.

There are a plethora of anecdotal reports of sensory processing difficulties in autism but not a great deal of scientific evidence. One key issue is to establish whether there are sensory processing difficulties that are universal in, and/or unique to, autism and, if so, to investigate the nature and possible causes for them. It is important, for the understanding of autism, to know whether sensory issues are prime, leading to other problems, for example, in perception, or whether they are secondary to other problems such as in attention. It is also important to understand these difficulties in order to develop the most helpful remediation and compensation strategies and to evaluate them.

Historical Background

Dual Autism Plus Sensory Impairment Diagnoses

Hearing Impairment The sensory processing problems associated with autism sometimes mean that infants may be unresponsive to sounds – especially social sounds like speech. As a result, it is common for hearing impairment to be first investigated as a possible cause for the differences in development noted by parents. This may arise from a genuine confusion of the symptoms of autism with deafness or it may be a simple precaution to rule out this sensory impairment before an autism diagnosis. If the child is found to have a significant hearing impairment but also has autism, clinicians and parents may believe the hearing loss is the cause of all the child's problems, and it may be many years before the dual

disability is fully acknowledged. This can mean that the child misses out on the most appropriate forms of education and support. The teaching of communication forms such as sign or symbol language may be less successful than in children with a sole hearing impairment because parents and staff have not recognized that the child will not learn to communicate just by being given the means to do so; in autism, the child needs to be taught directly about communication first. In such situations, it is common for the child to become frustrated and to develop secondary problems of social isolation and challenging behavior, making developmental progression even more problematic.

As long as the autism is recognized, and strategies put in place to teach and support the child in "autism-friendly" ways, there are many symbiotic features in hearing impairment and autism that mean that placement in services for the hearing impaired can be successful for the child with the dual problem. In countries like the UK, schools for the deaf, and peripatetic teachers of the deaf, were one of the earliest special educational services developed, and parents get regular in-home support. The growth of inclusion has been very successful for most children with hearing impairment, however, and cochlear implants have meant many now receive education through oral means. Much support has switched to mainstream schools, where the majority of such children are now educated. The children who have been least successfully integrated, and remain in the special schools, are those with multisensory impairments and comorbid conditions. Increasing numbers of children in these schools now have autism. Initially, they were children who had dual diagnoses, but, as schools developed expertise in working with children with autism, numbers of children with autism alone attend these schools. Staff expertise in using visual methods of instruction, having a clear and calm structure and concentrating on teaching communication, have all been helpful for these pupils with autism.

Visual Impairment The symptoms of autism are often missed in children with the dual disability because of some overlap in the development of autism and blindness. In children who are

congenitally blind, it is clear that visual social signals (like eye contact, visual joint attention, imitative smiling, and facial expressions) will be absent. This can lead to an asocial pattern of development that is akin to that of autism (Pring 2004), and even the repetitive stereotypies are often seen as what are called “blindisms.” Children who are just blind, however, will develop compensatory behaviors such as auditory and tactile joint attention, but this does not happen if they also have autism. Once again, services for the visually impaired have been the earliest to develop in many countries because the differences in development are marked and it is clear that parents and teachers will need knowledge, training, and support to help the child develop in the best way for him/her. No one expects the blind child to act as if she/he can see; it is accepted that education and other services must adapt to the needs of the child.

In that way, the child with the dual disability of autism and visual impairment in a setting for the visually impaired will at least have the advantage of staff who accept the difference and foster the child's attempts to do what best suits him/her, but in other respects, this is not a good environment for the child with autism. Auditory processing and tactile difficulties mean that most children with autism learn best from visually mediated structure and do not do well where touch guidance or verbal instruction (speech) is used, without visual support. Specific (e.g., nonsocial tactile) alternatives to visual mediation need to be developed. Technological aids are beginning to transform the teaching of communication and other academic skills to people with visual impairment (especially if there is some residual sight), and these have been helpful for those with autism as well. However, it is best if staff are trained to distinguish blind from autistic development and can develop strategies to support the dual disability.

Sensory-Motor Impairment and Cerebral Palsy Severe forms of cerebral palsy such as spasticity and athetosis will usually be diagnosed early, and so differences in development caused by autism may at first be missed in the

concentration on the physical problems of controlling movement. Parents may attribute all difficulties to the cerebral palsy, and it is not until the child joins groups of others who have cerebral palsy without autism that the autistic differences are recognized. In services that rely on methods of physical manipulation to engender movement in children with cerebral palsy, the autism may make it harder for the child to benefit from the therapy because of difficulties with being touched and the continual need for others to assist with everyday life. If the methods used are more functionally based (as in Conductive Education), then the physical arrangement of the environment to encourage independent movement may suit the child with autism so the dual disability is not so much of a problem. Cerebral palsy, however, will make it harder for the child to show independent actions and so the child is more dependent on communication to get needs met. This is a problem in the dual disability in that communication is a core difficulty in autism. Yet, the fact that the child needs to communicate may provide extra communicative pressure to help the child acquire communication skills, as long as staff are skilled in preventing frustration and the development of challenging behavior. The core difficulty in cerebral palsy is control of motor movements, but there are also often additional cognitive problems that interfere with development. The interaction with autism adds to the complexity and makes it even harder to determine and meet individual needs.

In less severe forms of sensory-motor impairment, the effects may be subtler but also more difficult to understand and allow for. Ataxia (where the child is generally clumsy and has problems in balance) may exacerbate sensory processing problems characteristic of autism. However, the child with a dual disability may benefit from the support of a skilled physiotherapist or occupational therapist, whereas the “minor” motor problems of the child with autism alone may be neither understood nor treated.

Dyspraxia (a problem in the planning and control of voluntary movements) is often found as comorbid with autism. Unless dyspraxia is understood, the child who can perform actions when

they are “triggered,” but not when directed to (because that involves planning), is likely to be misunderstood as deliberately noncooperative. In the context of autism, especially, dyspraxic difficulties are often seen as a matter of motivation and will, and so are never addressed as a motor problem, where help is required.

Sensory Processing Impairments in Autism

The Personal Perspective Problems in sensory integration in autism have been long recognized, and many people with autism themselves describe their condition almost solely in terms of these sensory difficulties. In this view, supported by some professionals, (e.g., Shanker 2004), it is because of problems in integrating senses, and hypersensitivity to certain sensory domains, that individuals with autism quickly become overwhelmed by sensations, making it difficult to make sense of the world around them. In other words, sensory problems lead to perceptual problems. This does not account for cases of apparent hyposensitivity – a lack of responsiveness to sensory stimuli. One suggestion is that when thresholds are low, there is a biological reaction to overstimulation of “shutdown,” leading to very high thresholds. Eventually, a balance is reached, and the person can function again, until whatever hormonal or neural response, causing the lowering of the sensory threshold, begins again. This would mean fluctuating sensory reactions. If such a cycle of over- to under-sensitivity is a reality, it would be difficult to adjust to the environment itself but necessary to give the person as much proximal control as possible (headphones to wear to block out or dampen unpleasant noise, hats or colored lenses in glasses to reduce glare, soft clothing to wear, and the freedom to remove shoes when necessary) so they are able to manage their own environment as far as possible. All this comes from anecdotal accounts of people with autism themselves, albeit compellingly and vividly described. Even accepting the validity of the experiences, the mechanisms underlying them are

speculative, and some people seem to be relatively permanently over- or under-sensitive with respect to certain stimuli, rather than going through such cycles.

An alternative view of what is occurring in autism is that the central core difficulties are at the psychological level, making it a failure in perception that causes individuals with autism to perceive all the overwhelming details of sensory stimuli instead. There are no easy answers to this “chicken and egg” dilemma. It may rest with neurological testing eventually to make this decision. What is clear at a practical level is that both processes are important. When the environment is adapted to reduce sensory overload, the person with autism seems better able to think and make sense of it. Alternatively, when people with autism are taught to be better at chunking information and at forming concepts and categories, they are better able to make sense of their world and not be so overwhelmed by sensory stimuli.

The Beginnings of a Scientific Approach Attempts have been made to classify the sensory responses in autism so they can be quantified and two important questions addressed: (1) Is there a pattern of stimuli responsiveness that is characteristic of all individuals on the autism spectrum? (2) Do individuals on the autism spectrum differ from typical peers or individuals with other disorders in their responses to sensory stimuli? Dunn (1999) produced a sensory profile from a questionnaire to parents or carers, where responses are given on a Likert scale of frequency (always, sometimes, seldom, never) to questions about particular reactions to everyday sensory stimuli. Dunn measures 125 items grouped into 9 factors (10, if the category “other” is included) and 14 sections. Scores are compared with a standardized “regular” mean and responses are classified as:

- “Typical” – at or above 1 standard deviation below the mean
- “Probable difference” – between 1 and 2 standard deviations below the mean
- “Definite difference” – more than 2 standard deviations below the mean

Sensory Impairment in Autism, Table 1 Sensory sections (Adapted from Dunn 1999)

Sensory processing	Modulation	Behavioral/emotional
1. Auditory processing	1. Sensory processing related to time/endurance	1. Emotional/social
2. Visual processing	2. Modulation re body position and movement	2. Behavioral outcomes of sensory processing
3. Vestibular processing	3. Modulation of movement re activity level	3. Thresholds for responding
4. Touch processing	4. Modulation of sensory input affecting emotions	
5. Multisensory	5. Modulation of visual input affecting emotions and activity level	
6. Oral-sensory		

The sections are further grouped into “sensory processing,” “modulation,” and “behavioral/emotional” (Table 1).

Alongside these are 9 (10) factors:

- 1. Sensation-seeking
- 2. Emotionally reactive
- 3. Low endurance/time
- 4. Oral sensory sensitivity
- 5. Inattention/distractibility
- 6. Poor registration
- 7. Sensory sensitivity
- 8. Sedentary
- 9. Fine-motor/perceptual
- 10. Other

The purpose of the sensory assessment is to build a sensory profile of the individual. This scale is relatively objective (reporting norms, levels of reliability, and validity) allowing comparison of individuals with autism to others and, within the scale, to identify particular patterns of sensory disturbance. This profile is based on a broad range of sensory processing that might be affected in autism although it does not include proprioceptive sensations, which allow one to get feedback on actions and monitor the position of one’s body in space. People with autism describe difficulties in this kind of processing, and it would help account for some of the problems in making goal-directed actions in some individuals with autism and in being aware of one’s own intentionality.

Nor does it mention the processing of pain, for which there is conflicting evidence. Anecdotal reports, of a high pain threshold or an extreme delay in registering pain, are not supported by the little scientific evidence that exists (Nader et al. 2004). An absence of, or delay in experiencing, pain would make it very difficult for the child to connect the actions that lead to an injury with the experience of pain, and so the child might well repeat dangerous actions regardless of consequences. However, failure to report pain may be due to social or communication differences or fear of the “sensory and social onslaught” that comes from comforting. There is certainly anecdotal evidence of recklessness in some individuals with autism but the lack of responsiveness to social restraint may be key to that. It is possible that there is a synesthesia effect in autism in that other sensations, which are typically benign, may cause pain. Thus, some taste, touch, and auditory sensations have been reported as painful by adults with autism.

There are other profiles, used by practitioners to help their understanding of what may be happening in individuals, to plan effective programs for learning and to help avoid challenging behavior. Bogdashina’s (2003) sensory profile includes as additional items “literal” perception, “Gestalt” perception (inability to distinguish background from foreground information), inconsistent/fragmented/distorted perception, sensory agnosia, delayed perception, and vulnerability to sensory overload. These categories have good

face validity for those who live and work with those with autism, but the items are often hard to operationalize, so comparisons across scorers and individuals are hard to establish. Bogdashina describes different perceptual styles as “monoprocessing,” “peripheral,” “system shut-down,” “compensatory,” “resonance,” and “day-dreaming.” She goes on to describe different cognitive styles as “subconscious,” “unconscious,” and “preconscious.” Finally, Bogdashina talks of some particular sensory processing issues which have been said to characterize (or at least be common within) autism: these are “synesthesia,” “central auditory processing disorder” (CAPD), “scotopic sensitivity” or “Irlen syndrome” (a disorder whose existence is controversial), and “sensory integration dysfunction.” Many of these supposed sensory disabilities are tied to particular treatment approaches, so caution is needed to establish their validity as concepts before evaluation of treatments is undertaken.

Current Knowledge

Dual Diagnoses of Sensory Impairment and Autism

More children with sensory impairments are receiving a dual diagnosis of autism with a sensory disorder, although the confusion over early signs remains. Children with “pure” sensory impairment continue to be more likely to be educated in mainstream environments, and special schools retain those with multiple, more complex disorders. As Jordan (2011) has argued, specialist education for children with autism is not about location but primarily about the knowledge and skills of staff. More teachers of the visually and hearing impaired are recognizing their need for additional training in understanding and working with children with autism, when faced with the dual disability. There has been no evaluation of the different placements for such dual-diagnosed children; it might be expected that where a hearing impairment is involved, the school for hearing impaired children (with additional training and resources) would be successful, whereas there would need to be greater adjustments in the

teaching of children with the dual diagnosis of autism and visual impairment compared to those with visual impairment alone. However, this is an empirical question that has not yet been addressed. A method of communicative assessment and treatment for children with severe autism (COMFOR: Noens, Van Berckalaer-Onnes, Verpoorten & Van Duijn (2006) has been developed and the same team are now developing a version for children with an additional visual impairment).

Sensory Dysfunction Within Autism

Evidence for a Sensory Dysfunction as Part of Autism Early studies suggested that children with autism could be distinguished from children with developmental delay and typically developing children on the basis of abnormalities in sensory functioning. Some showed differences in early sensory-motor behavior (under 1 year) that could distinguish those who were later typically developing, intellectually impaired, or had autism (Baranek 1999). Most of the studies have compared the scores of children with autism with those of typically developing children or children with other disorders (or both) on Dunn’s Sensory Profile. Most have found significant differences, on at least some categories. However, many of the findings are contaminated by using children from a wide age range, when there are known age differences in sensory modulation with age. Participants also need to be matched for developmental age (or there need to be two comparison groups) since those with intellectual impairment also show differences in sensory modulation from the typical. Rogers and Ozonoff (2005) review the evidence and conclude that there are some differences between children with autism and typical children (and sometimes other groups as well) but little consistency on the nature and extent of these differences. The most consistent finding is of greater under-responsiveness in children with autism spectrum disorders. Miller et al. (2005) examined sensory processing in children with a diagnosis of Asperger syndrome or High Functioning Autism. They classified their sample into three different responsivity groupings: 1.

Sensory over-responsivity; 2. Sensory under-responsivity; 3. Sensory seeking. They also found they could be divided into 'low' versus 'high' arousal groups and 'sensory habituators' versus 'non-habituators'. However, recent studies have queried the value of such grouping across different sense domains. Ben-Sasson et al. (2009) conducted a meta-analysis of studies of sensory disturbances in autism and established that such disturbances were both multi-modal and variable. They also found that sensory disturbances were universal across the autism spectrum. Young children with autism were found to be more likely to be hypo-responsive or non-responsive but not sensory seeking. Older children and adults were more likely to be hypersensitive but were also more likely to be sensory seeking. This suggests a variable pattern of responsiveness to sensory stimuli across different domains and no simple relationship between sensory sensitivity and sensory seeking or avoidance.

The full form of the sensory profile contains items that pertain to core areas of autism so it is not surprising that differences in these areas would occur. The short form is better in that it excludes social, communication, and motor responses. Dunn and Daniels (2002) have produced a short form specific to toddlers and infants, and this has been used, with other measures, in a comprehensive study by Ben-Sasson et al. (2007), which sought to address some of the methodological weaknesses of the earlier studies. They used comparison groups matched for chronological and mental age and not only the Dunn toddler profile but other parent-report scales and direct observations. They found consistency in parent reports across different measures but a poor correlation between parental report and direct observations. The most consistent finding was in the extremity of the responses in the autism group compared with controls with a high frequency of unresponsiveness to sensory stimuli and high levels of avoiding behavior, as well as low levels of sensory-seeking behavior. In interpreting their findings, however, they point to the fact that many of the scales, as with the full sensory profile, use social stimuli (e.g., avoids eye contact) to judge sensory responses,

and, by definition, these will be different in autism.

Crane et al. (2009), using the Adult Adolescent Sensory Profile (AASP), a shorter self-report questionnaire, found that the scores of adults with autism differed significantly from the typical in four areas. Those with autism scored more highly on "low registration," "sensory sensitivity," and "sensory avoiding" but had lower scores on "sensory seeking." The most extreme differences were in "sensory avoidance." There were correlations between the scores and IQ but no correlation with age or degree of autism. Thus, there appears to be some support for sensory differences in autism that persist in time, but there is little evidence that the sensory differences lead to autism in any way.

A recent comprehensive study of sensory processing in autism by Lane, Young, Baker and Angley (2010) used a model-based cluster analysis approach to examine sensory processing subtypes in 54 children with autism and to relate them to different levels and kinds of adaptive functioning. They claim to have revealed three subtypes of sensory functioning which predicted communicative competence and maladaptive behaviour. While admitting limitations of the study in that small numbers were involved and the measures came from a parental questionnaire, the authors suggest that the results from the model they used allow more specific questions to be posed, which should yield more scientific data in the future. They found overall significant differences between the children with autism and typically developing children in the degree of under-responsiveness, the number who were seeking sensation and (in 92% of the children) those with problems in auditory filtering. They used measures across different sensory domains and compared specific data rather than producing generalized 'sensitivity' classifications.

The classifications found in the Lane et al. study (op cit) were based on sensitivities in particular domains: 1. Sensory-based inattention and sensory seeking (SBIS); 2. Sensory modulation difficulties in movement (SMMS); 3. Sensory modulation difficulties in taste/smell (SMTS). The SBIS group only had mild sensory processing

problems and these were related to the behavioral issues of inattention, distractibility, over-focused attention and impulsivity. The SMSS group had wide sensory modulating difficulties across most domains; there were cases of both over and under sensitivity. They had problems with motor sensitivity and extremely low scores in the low energy/weak domain. The behavioral relationships were with low muscle tone, weak grasp and easily tiring. Finally, the SMTS group has sensory modulation difficulties in taste/ smell particularly but across all domains except the motor. This group was associated with the greatest problems in communication. There was a general relationship found between the degree of sensory function and challenging behavior with taste/smell sensitivity, auditory filtering and movement sensitivity all being related to particular patterns of challenging behavior.

Interventions for Sensory Dysfunction in Autism Dawson and Watling (2000) reviewed research evidence of the effectiveness of different treatments to address the sensory problems in autism. They examined the three areas where most treatment has been undertaken: (1) auditory integration therapy, (2) sensory integration therapy, and (3) occupational therapy for sensory dysfunction (as distinct from occupational therapy directed at building functional skills). Auditory integration therapy is directed at the presumed deficits in auditory processing in autism. The aim is to get the child to “relearn” how to listen by taking him/her through specially selected sounds presented through earphones several times a day over a period of a few weeks. Many claims have been made about the effects on behavior and even reduction (sometimes “elimination”) of autistic symptoms. However, as Dawson and Watling report, in all but one of the studies, the children who had undergone AIT did no better than “placebo” controls. The one study showing beneficial effects was the least satisfactory in its methodology.

Sensory integration therapy is a program of controlled sensory experiences involving vestibular, proprioceptive, and somatosensory activities. The activities themselves include swinging, deep pressure touch, and tactile stimulation. There were few methodologically sound studies of sensory

integration therapy, most reports being of very small case studies over short time frames. In addition, the more rigorous the research design, the smaller the beneficial effect noted.

Finally, although occupational therapists are heavily involved in treating children with autism for sensory integration problems, Dawson and Watling could find no scientific evaluation of their work.

Neurophysiological Support for Sensory Dysfunction in Autism If sensory dysfunction is a core part of autism, one would expect to find it in studies of the neurology of sensory processing as well as in behavior (Table 2). Maro et al. (2011) have recently reviewed these findings. They look at studies that have concerned auditory, tactile, visual, and multisensory stimuli and used measures such as EEG (electroencephalography), MEG (magnetoencephalography), and fMRI (functional magnetic response imaging).

These findings, therefore, suggest that behavioral differences in responses to sensory information are reflected in neurophysiological differences. The results are not consistent enough for a definitive picture to emerge but there is evidence of some differences. Maro et al. (2011) interpret these findings with caution. They point out that other mechanisms, such as attention, which are known to be affected in autism, may influence these findings. There is evidence of problems with attention shift in autism but only with those who have additional learning difficulties. It also appears that individuals with autism can overcome their difficulty in switching attention to speech tones away from other complex tones by direct instruction to attend to them. Similarly, problems with selectively attending to certain stimuli in autism vary according to the intensity and complexity of the stimuli, and it is only in complex situations that individuals with autism are less able than others to respond to a sound source. Thus, the difficulty may lie with inhibiting reactions to other stimuli as much as with attention to the target stimulation.

Conclusions Regarding Sensory Dysfunction and Autism This is an area of great mismatch between practice and established science. There

Sensory Impairment in Autism, Table 2 Summary of findings of sensory processing in autism at neurophysiological level

Auditory	Tactile	Visual	Multisensory	Higher multisensory
There are many inconsistent findings, but there is good evidence of significant differences in speech sound processing. Some evidence of atypical processing in the primary auditory cortex	The results suggest some specific hypersensitivities in autism. There were enhanced responses to low-level vibration. Some hypersensitivity to vibration and heat but not to light touch	Better responses to detail when stimuli are simple but general impairment with complex stimuli. Also some problems with spatial discrimination. Face recognition is impaired but depends on familiarity, attention, gaze direction, fixation, and type/complexity of stimuli. Children with autism better than typically developing at processing detailed high spatial frequency stimuli and worse at rapid low-frequency processing. Differed in emotional responses to faces in amygdala and cortex	Some differences in the processing of visual auditory illusions, which suggests individuals with autism may be less efficient at multisensory integration. Problems in autism when auditory and visual stimuli presented together – leading to delay in processing at the second stage	Most significant difference found is in the integration of audio and visual information in the reception of speech. Individuals with autism appear to depend more on the auditory perception of phonemes, divorced from their lip patterns, and training has little effect on this. Practically this could lead to problems in speech perception in noisy environments where lip patterns would normally serve as a discriminatory cue. Findings suggestive of problems in autism in the connections between cortical and subcortical regions of the brain

is a wealth of anecdotal evidence of sensory processing problems in autism but very few scientific “facts” have been established. It appears that sensory processing is neither uniformly good nor bad in autism, but rather depends on the nature and complexity of the signal, the background stimulation, and the directions given. The uncertain picture at the behavioral level is mirrored at the neurophysiological level, although specific difficulties in connecting vision with sound, especially in relation to speech, do seem to be firmly established.

Future Directions

Dual Sensory Impairments and Autism

The current situation, described above, where children with “pure” sensory impairments are increasingly educated within the mainstream is

likely to continue. With technological advances in the treatment of sensory impairments and in providing tools to access the mainstream curriculum, however, those with more complex multisensory impairments and/or dual diagnoses may also come to be included in the mainstream, so that the existence of schools and services specific to particular sensory impairments becomes problematic. There will still be a need for qualified staff to support and educate families, vocational, and social care staff and to provide peripatetic support to schools, but it may become difficult for staff to gain experience (and therefore, expertise) in the sensory impairment. This in turn will affect the services available to individuals with autism and a comorbid sensory impairment. It will no longer be a matter of adding autism training to staff already experts in sensory disability but perhaps a need for “de novo” training in such dual disabilities. Since such dual disabilities are

relatively rare, such services may need to be centralized and with that will come accessibility issues and the possible reemergence of residential segregated schooling. Lifelong support may also deteriorate as relevant expertise becomes scarce.

Sensory Processing Disorder and Autism

The present dearth of scientific evidence on the nature and extent of sensory dysfunction as part of autism is likely to change in line with the changes in DSM-V. Diagnoses, even of just “associated features” of autism, cannot just rely on anecdotal evidence. The current sensory profile assessment tools will need to be adapted so they have greater validity, especially when some research suggests that parents of children with autism are not accurate reporters of their child’s sensory experience. Adult profiles circumvent this problem but have the additional problem of only being accessible to those above a certain level of intellect and ability to communicate. Some research already suggests that low- and high-functioning individuals with autism (in terms of adaptive skills) differ in sensory responsiveness, and those who have least sensory problems are liable to do best in acquiring academic and adaptive skills, including communication. It may be that the validity of behavioral sensory profiles will need to be validated against neuropsychological “direct” testing of sensory processing in individuals with autism and others.

Whatever profile is used, the terms need to be operationalized to give greater reliability. A priority will be areas where there is already some good evidence of sensory difficulties: auditory and tactile stimuli. Once valid and reliable tools for measuring sensory processing are available, the validity (or otherwise) of sensory processing differences in autism will need to be established by good scientific comparison studies across the senses of vision, hearing, taste, touch, smell, proprioception, vestibular sensation, and pain. There may also need to provide data across different domains since it appears that generalized “sensitivity” scores are not as useful as measures of sensitivity within different sense domains. Multisensory integration will also need to be studied, through carefully constructed tasks that clearly depend on such integration, as will unusual phenomena such as synesthesia.

However, finding (or refuting) differences in sensory processing in autism is only the start. Any such differences will need to be interpreted and investigated in terms of their relationship to other possible confounding variables: the role of attention shift and selective attention differences in autism, the differences in communication, emotion processing, social referencing, and processing of cognitive complexity. Once a clearer picture emerges of the nature of the differences in autism processing, there needs to be an analysis of the extent to which “differences” can be equated with “difficulties,” which might then be candidates for remediation. Only once the clear targets for treatment have been set does it make sense to evaluate treatments (or perhaps develop new treatments for evaluation). Treatments could then be evaluated in terms of their research rationale as well as efficacy, in line with good practice (Jones and Jordan 2008). Occupational therapy needs to develop as a profession to include this kind of evaluation of practice if it is to demonstrate its value beyond the level of anecdote.

Sensory Integration (SI) Therapy

Tara J. Glennon
Occupational Therapy, Quinnipiac University,
Hamden, CT, USA
Centre of Pediatric Therapy, Fairfield and
Wallingford, Wallingford, CT, USA

Definition

Sensory integration therapy, guided by sensory integration theory originated by Dr. A. Jean

Ayres (1979), is commonly utilized by occupational therapy practitioners (additional information found under A. Jean Ayres in the “[See Also](#)” section below). Although many professionals outside the field of occupational therapy have declared that their intervention techniques are “sensory integration,” their practices do not correspond to the theoretical principles researched by Dr. Ayres and her occupational therapy colleagues, nor do they result in an adaptive or purposeful response and improved engagement in occupation (Roley et al. 2007). As a result of this encroachment on the term sensory integration, the successor trustee of Dr. Ayres estate (Baker/Ayres Trust) trademarked the term Ayres Sensory Integration® (ASI) thus allowing consumers to be assured that they are acquiring the sensory integration services intended. In order for occupational therapists to identify their use of ASI, the term OT/SI is recommended.

Sensory processing difficulties are noted in many diagnostic categories, as well as in children with no other clinical or developmental concerns. However, there is a high incidence of sensory processing impairments in children on the autism spectrum. For this specific population of individuals, Ayres Sensory Integration intervention is different from simply providing sensory activities as a reward for appropriate behavior or desired performance during discrete trial programs, moving an individual into a “time-out” room which houses sensory equipment, or providing strategies throughout the day to keep the child calm and focused (i.e., sensory diet). In fact, it is well understood by occupational therapy practitioners that ASI is done within the context of play and that engagement in the play experience is its own reward because the play is meaningful to the child. As the aim of occupational therapy is to support an individual’s participation in life through engagement in occupation (American Occupational Therapy Association [AOTA] 2008), the therapeutic intervention outlined by the occupational therapy practitioner using an Ayres Sensory Integration approach is child specific based on the child’s sensory processes and how these processes are barriers to, or facilitators of, participation and engagement in life activities identified as priorities by the family and team.

Two specific areas of attention with this population include:

- **Praxis:** the process of action performance requiring ideation, planning, execution, and sequencing (May-Benson 2004)
- **Modulation:** maintaining a functional state of alertness and regulating the degree, intensity, and nature of responses to a sensory event (Miller 2006)

It is also important to note that occupational therapy practitioners utilize an ASI approach in combination with other theoretical frameworks. An official statement by the American Occupational Therapy Association (AOTA 2010, p. 4) regarding intervention for individuals on the autism spectrum cites: “Effective interventions also address contextual factors such as structure, consistency of routine, sensory environments that optimize attention and arousal, and caregiver skills that contribute to occupational performance. Research evidence indicates that the occupational therapy intervention process should be individualized, intensive, and comprehensive; include the family; and facilitate active engagement of the individual” (Tomchek and Case-Smith 2009). This document goes on to highlight the underlying sensory processes that should be assessed for this population: “sensory modulation, self-regulation, praxis, and motor imitation” (p. 4). Additionally, Ben-Sasson et al. (2007) emphasize that in order to accurately identify the needs of very young children on the spectrum, occupational therapists need to assess multiple components of the child’s sensory functioning across varying contexts in order to fully understand and support the impact on the child’s performance and the family’s life.

Historical Background

Ayres original theory of sensory integration (Ayres 1972, 1979) described what was referred to as a scientific theory. That is to say that as more research is conducted, technology

becomes available to scientifically measure the underlying theoretical constructs, and outcome information is obtained, the theory would evolve to inform practice. This concept has also been described as the scientific evolution of the sensory integration frame of reference (Schaaf and Davies 2010).

Ayres began her work in this area in the 1950s, coined the term sensory integration in the 1960s, and culminated her work with the publication of the Sensory Integration and Praxis Tests (SIPT; 1989). While there has been some change in the terminology used to describe the diagnostic categories identified through this comprehensive assessment tool (refer to the Sensory Integration and Praxis Tests in the “[See Also](#)” section for full review), the intervention strategies utilizing Ayres basic tenets have not changed. The theory espouses that improving sensory integrative functions leads to adaptive responses (purposeful actions in response to an environmental demand) allowing the child to engage more fully in everyday life tasks or occupations (i.e., play, learning, daily living tasks).

Rationale or Underlying Theory

Dr. Ayres work, based on neuroscience, psychology, education, biology, and occupational therapy, hypothesized that underlying difficulties with integrating sensory information can lead to learning and behavior difficulties (Ayres 1972). The three major postulates of sensory integration theory are:

1. Learning is dependent on the ability to take in and process sensation from movement and the environment, and use it to plan and organize behavior.
2. Individuals who have a decreased ability to process sensation also may have difficulty producing appropriate actions, which, in turn, may interfere with learning and behavior.
3. Enhanced sensation, as a part of meaningful activity that yields an adaptive interaction,

improves the ability to process sensation, thereby enhancing learning and behavior.

The basic assumptions of the theory are that the nervous system is plastic, sensory integration develops, the brain functions as an integrated whole, adaptive interactions are critical to sensory integration, and people have an inner drive to develop sensory integration through participation in sensorimotor activities. Lane and Schaaf (2010), in their article examining the neuroscience evidence supporting or refuting the implementation of OT/SI, stated (p. 375): “OT/SI is based on the belief that engagement in individually tailored activities, rich in the needed sensory stimuli, will improve the ability of the brain and nervous system to process sensory information, enhance the organization and integration of sensation, and, as a result, have a positive impact on the child’s ability to participate in daily life activities (Ayres 1972, 1979).” After reviewing the neuroscience literature, Lane and Schaaf go on to state: “There is little question that the nervous system is plastic and that sensory input is an important mediator of this plasticity. Motor activity and interest in task also appear to be important contributors, and active engagement is seen to enhance the effects. Moreover, these studies indicated that neuroplastic changes were developmental, dynamic (reactive), and task specific. In this regard, these data provide indirect support for the use of OT/SI, which is built on the premise that active engagement in meaningful, sensorimotor activities at the just-right challenge and in a playful or meaningful context has a positive impact (by means of neuroplasticity) on processing in the nervous system (Ayres 1972).”

Goals and Objectives

Despite the intervention chosen, the goals and objectives of occupational therapy intervention are the same. According to the AOTA’s statement on the scope of services for individuals on the autism spectrum (2008, p. 4):

Assessing the outcomes of service is an integral part of the occupational therapy process and is important for determining future actions and for evaluating occupational therapy services provided for the individual, organization, or population. This assessment involves monitoring the client’s responses to intervention, reevaluating and modifying the intervention plan, and measuring intervention success through outcomes that are important to the client within the dynamic physical and social environments and cultural contexts where functioning occurs. Progress is noted through improvement in the client’s occupational performance, adaptation, participation in desired activities, satisfaction, role competence, health and wellness, and quality of life and through prevention of further difficulties and facilitation of effective transitions. Occupational therapy practice for individuals with an ASD is consistent with the WHO’s (2001) *ICFg* and the National Research Council’s 2001 recommended practices for educating individuals with an ASD.

For OT/SI specifically, the intent of therapeutic intervention is to assist the individual in receiving, processing, correctly interpreting, and integrating sensory information as a foundation for improving functional participation in life’s tasks. It is important to note that these underlying skills, rather than simply training of a child’s functional difficulties, are the focus of this intervention approach. The maturation and development of these underlying substrates of dysfunction are then measured via praxis (motor planning) and modulation abilities which impact functional participation, learning, and behavior. In addition, since the sensory processes of a child on the spectrum also affect the family’s routines and social participation (Bagby et al. 2012), this area also needs to be supported by the occupational therapy practitioner. For example, Bagby, Dickie, and Baranek’s research identified that chosen activities for the family are often influenced by the child’s tolerance to sensory experiences, the amount of planning that needs to occur prior to participation in life’s activities is significant, and the ability to create family memories is often compromised as parents need to split up during family outings.

Treatment Participants

Occupational therapy practitioners, with advanced training in ASI, will often refer to their intervention as OT/SI to indicate utilization of this specialty approach. This approach is a dynamic exchange between the OT/SI practitioner and the child/individual with sensory processing concerns. Additionally, the collaboration with family and school personnel is critical for the generalization of treatment outcomes.

Treatment Procedures

In addition to Ayres writings (Ayres 1972, 1979), sensory integrative interventions have been described and discussed in texts intended to improve the clinical reasoning skills of clinicians (Bundy et al. 2002; Fisher et al. 1991) and numerous articles in the occupational therapy literature. Schaaf and Miller (2005) highlight how astute observation of the child's ability to process and utilize sensory information is a key skill of the well-trained therapist.

In order to clearly delineate the components of this intervention approach, a group of occupational therapy researchers (Sensory Integration Research Collaborative [SIRC]) detailed the required elements of intervention (Parham et al. 2007, 2011). While the original intent was to provide a mechanism to assure fidelity (truthfulness) to the theoretical principles during the intervention phase of research studies, the secondary benefit was that occupational therapy practitioners were provided with a framework to understand what is and what is not Ayres Sensory Integration intervention.

The Ayres Sensory Integration Fidelity Measure (Parham et al. 2011, pp. 135–136) outlines the following components for this occupational therapy approach:

- The therapist should have post-professional training in sensory integration which includes a minimum of 50 education hours of SI theory and practice (e.g., post-professional SI or SIPT certification or university course) and ongoing

supervision (minimum of 1 h per month) by an expert with at least 5 years experience providing occupational therapy using SI intervention.

- The occupational therapy assessment report should include information-related occupational therapy principles (AOTA 2008) including historical information, reason for referral, an occupational profile, and performance patterns.
- The occupational therapy assessment report should include information related to specific sensory patterns and processes, including sensory modulation and discrimination, postural/ocular control, visual-perceptual skills, fine and gross motor skills, motor coordination, praxis, organizational skills, and the influence of sensory integration and multisensory processing on performance, as well as an interpretive summary describing the effects of sensory integration and praxis on the referring difficulties.
- The physical environment in which the ASI intervention should occur includes adequate space for the flow of the intervention including vigorous physical activity; equipment and materials which can be flexibly arranged to adjust to the rapid changes which occur during the course of intervention and the varying size of the child; no less than three hooks for suspended equipment (with adequate spacing for full orbit); availability of rotational devices (to allow for 360° of rotation) and bungee cords; mats/cushions/pillows for safety; a variety of equipment for sensory experiences, e.g., bouncing equipment, therapy balls, a variety of swings, scooters, ramps, climbing equipment, weighted objects, ball pit, barrel, spandex fabric, vibrating toys, tactile material, visual targets, and props to engagement in play; and a quiet space.
- Communication with parents and teachers to support goal setting as well as to allow for discussion of the potential influence of sensory integration and praxis on performance in valued activities; the child and family's participation in home, school, and community; and how the therapist defines the areas to be addressed that will improve engagement.

- During the intervention process, the therapist should:
 - Ensure the child's physical safety by anticipating physical hazards and be in close physical proximity during activities.
 - Present the child with tactile, vestibular, and proprioceptive opportunities to support the development of self-regulation, sensory awareness, and/or movement in space.
 - Help the child attain and maintain appropriate levels of alertness and an affective state that supports engagement in activities.
 - Collaborate on activity choices with the child.
 - Support and challenge postural control, ocular control, and/or bilateral development through the use of postural, resistive whole-body, ocular-motor, oral, or bilateral challenges, as well as projected action sequences.
 - Challenge praxis (ability to conceptualize and plan novel motor tasks) and organization of behavior in time and space.
 - Tailor the activity to the just-right challenge by increasing the complexity of the challenge when the child responds successfully.
 - Ensure that activities are successful and, thus, the child is making an adaptive response to the presented challenges in sensory modulation or discrimination; postural, ocular, or oral control; or praxis.
 - Support the child's intrinsic motivation to play by creating a setting which supports play as a way to fully engage the child in the intervention.
 - Establish a therapeutic alliance which promotes and establishes a connection with the child and conveys a sense of working together in a mutually enjoyable partnership (vs. basic pleasantries or feedback on performance such as praise or instruction).

Efficacy Information

Unequivocal evidence on the effectiveness of Ayres Sensory Integration remains elusive for a

variety of reasons. This is not to say that occupational therapy practitioners do not see improvement in the children they serve, as there are numerous reports of progress via parental observations, improvement and mastery of identified goals and objectives, and small-scale studies with positive outcomes. However, gold-standard research outcomes have not been documented.

One difficulty with performing high-quality, empirically sound research is the confusion over what is and what is not Ayres Sensory Integration intervention. Several meta-analyses have been performed to review the literature on this topic, yet the actual interventions did not align consistently with the principles of ASI intervention. An early review by Ottenbacher (1982) found significant positive effects in motor outcomes for children with learning disabilities and mental retardation as compared to no treatment; Polatajko et al. (1992) found that the sensory integration intervention showed the best gains in motor performance for children with learning disabilities but that the SI intervention was no more effective than other interventions; Vargas and Camilli (1999) reported moderate effects in motor performance compared to no treatment but little difference as compared to other more traditional occupational therapy approaches (i.e., perceptual-motor approach); Hoehn and Baumeister (1994) reexamined some of the Polatajko, Kaplan, and Wilson's studies and found some positive outcomes but did not substantiate an SI approach as providing a more positive outcome than alternative approaches; and Baranek (2002), who looked specifically at sensory-based interventions for children on the autism spectrum, found that the small sample sizes and weak designs need to be considered when viewing the positive outcomes. In the most recent review, May-Benson and Koomar (2010) systematically reviewed, evaluated, and synthesized the findings of 27 articles on the effectiveness of sensory integration interventions found in the literature from 1972 through 2007. "Outcome areas examined were as follows: motor performance, sensory processing, behavioral outcomes, academic and psychoeducational outcomes, and occupational performance" (p. 406).

Since the last systematic review, several small studies related to the population of children on the autism spectrum have occurred. For example, a group of 37 children on the spectrum was studied in a design comparing sensory integration (SI) intervention to a fine motor intervention (Pfeiffer et al. 2011). While both groups improved on Goal Attainment Scaling, the SI group showed more significant improvement in the three domains of sensory processing, motor skills, and social functioning. Additionally, the SI group demonstrated fewer autistic mannerisms (as measure by a subscale of the *Social Responsiveness Scale*) than the fine motor group after the interventions. In another small study, Smith et al. (2005) reported positive effects of a sensory integrative approach on decreasing self-stimulating behaviors. Despite these efforts, large-scale, randomized control effectiveness studies have yet to be completed.

Another difficulty in designing research studies on the effectiveness of ASI is the underlying concept that the process is dynamic exchange between child and practitioner with the intervention specific to each child's particular combination of difficulties, thus operationalizing the variables within a research design presents a significant challenge. In an effort to address this and other methodological challenges, as well as definitively outline what are the core components of ASI, a team of researchers developed a fidelity measure for sensory integration research (Parham et al. 2007, 2011). This measure outlines both structural and process elements necessary for the intervention to be congruent with Ayres theory and thus designated as Ayres Sensory Integration. For research purposes, this measure allows for the manualization of the intervention – i.e., the precise description of the intervention components which are then consistently administered in order to have confidence that the outcome is the result of the intervention and the intervention can be reproduced in subsequent studies.

The Ayres Sensory Integration Fidelity Measure, which outlines the following components of providing ASI, has been found to have strong

content validity for the structural and process elements, thus representing the essential features of ASI intervention (Parham et al. 2011). Additionally, the process components are reliable and valid when scored by experts in ASI, but not when scored by practitioners without advanced training.

Structural elements (Parham et al. 2011, p. 135):

1. Therapist qualifications
2. Components of the evaluation/assessment report
3. Physical environment
4. Communication with the parent or teacher

Process elements (Parham et al. 2011, p. 136):

1. Ensure physical safety.
2. Present sensory opportunities.
3. Help the child attain and maintain appropriate levels of arousal.
4. Challenge postural, ocular, oral, and bilateral motor control.
5. Challenge praxis and organization of behavior.
6. Collaborate in activity choice.
7. Tailor the activity to present the just-right challenge.
8. Ensure that activities are successful.
9. Support the child's intrinsic motivation to play.
10. Establish a therapeutic alliance.

With this ASI Fidelity Measure, along with a manual outlining ASI's philosophies, principles, and strategies which is currently under development, it is hoped that more scientifically sound research on the efficacy and effectiveness of Ayres Sensory Integration is in the near future.

Outcome Measurement

See “Goals and Objectives” as functionally related outcomes are child specific.

Qualifications of Treatment Providers

There has been much discussion related to the qualifications of the treatment provider as it relates to Ayres Sensory Integration. As this theoretical approach was created by an occupational therapist for occupational therapists, the model of intervention is presented in all entry-level curricula for occupational therapists. However, there is variability between academic institutions in how the information is presented, to what extent the information is discussed and/or practiced, and the qualifications of the teacher within this area of practice. Additionally, as some physical therapists with a pediatric specialty also utilize this approach, the qualifications of the treating practitioner needed to be highlighted. The qualifications, while originally designed for research purposes, serve as a guideline for practitioners aspiring to provide professionally responsible ASI intervention. The Ayres Sensory Integration Fidelity Measure outlines the therapist qualifications to include (Parham et al. 2011, p.135):

- Post-professional training in sensory integration – certification in SI/SIPT: minimum of 50 education hours of SI theory and practice (e.g., post-professional SI or SIPT certification or university course)
- Supervision by an expert with at least 5 years experience providing occupational therapy using SI intervention (minimum of 1 h per month)

Years ago, there was a specialty certification that was offered by Sensory Integration International, the organization originally created for the advancement and dissemination of Dr. Ayres' work. After the passing of Dr. Ayres, and some internal difficulties, this organization ceased offering these courses. Currently, there is only one training series in order for therapists to be certified in the administration and interpretation of the Sensory Integration and Praxis Tests (SIPT), offered jointly by the University of

Southern California's Division of Occupational Science and Occupational Therapy and Western Psychological Services (USC/WPS) and approved by the Successor Trustee of Dr. Ayres' estate (holder of the trademark term Ayres Sensory Integration®).

This certification includes a series of four, 5-day courses:

- Theoretical foundations of sensory integration
- Technical and logistical administration of the SIPT as well as other commercially available measures of sensory processing
- Interpretation of the SIPT's standardized information and interfacing that information with other nonstandardized observations and reports of the child's performance in order to develop appropriate intervention plans
- Intervention planning based on the theory of sensory integration, including practical applications and clinical reasoning strategies

Please note, however, that the USC/WPS website does not list therapists who were certified by the original organization sanctioned to offer the Certification of the Administration and Interpretation of the SIPT. As a result, parents and professionals should not limit themselves to only those therapists registered with USC/WPS organization.

SIPT

Description

The *Sensory Integration and Praxis Tests* (SIPT; Ayres 1989) is a series of 17 subtests designed to measure sensory integration processes that underlie learning and behavior in children from 4 through 8 years, 11 months. This comprehensive, standardized assessment tool is considered the gold standard tool for evaluating sensory integration and praxis (motor planning) functions. Administration of the entire test generally takes 2½ h to complete, the examiner must follow specific procedures when administering the test (including what instructions can be provided to the child), and the child must be able to attend for long periods of time and follow the verbal directions. As a result, it may not be an appropriate testing instrument for all children on the autism spectrum.

There are 17 subtests within the SIPT, each yielding a standardized score by which the child's score is compared to those of typically developing children on praxis abilities and a variety of sensory processes, including tactile (touch), vestibular (movement/balance), proprioceptive/kinesthetic (where are the body parts in space and how do they work together), and visual (Table 1). The test focuses on how the child recognizes, discriminates, and perceives the sensory experience. It does not, however, have a specific scoring mechanism to identify if the child over- or underresponds to various sensory

experiences (referred to as sensory modulation, sensory underreactivity, and sensory overreactivity). For modulation type of information, please see the links below in the "See Also" section for the *Sensory Processing Measure*, *Sensory Processing Measure – Preschool*, and/or soon to be published *Sensory Processing Assessment*.

All SIPT results are scored via computer program, and while administering all 17 subtests is ideal, any combination can be implemented and still maintain the integrity of the standardized score. Following scoring, the computer generates a detailed report explaining the SIPT results. However, as the secondary purpose of the SIPT is to provide a foundational understanding of the child in order to outline appropriate intervention approaches, the ability to correctly implement and interpret the information provided by the SIPT is vital. Specialized training in the SIPT is not only strongly suggested and professionally responsible, but the therapist's name and professional qualifications are required in order to purchase the SIPT. Years ago, this specialty certification was offered by Sensory Integration International which was the organization originally created for the advancement and dissemination of Dr. Ayres' work. After the passing of Dr. Ayres, and some internal difficulties, this organization ceased offering these courses. Currently, there is only one training series in order for therapists to be certified in the administration and interpretation of the SIPT, offered jointly by the University of Southern California's Division of Occupational Science and Occupational Therapy and Western Psychological Services (USC/WPS) and approved by the Successor Trustee of Dr. Ayres' estate (holder of the trademark term Ayres Sensory Integration®).

This certification includes a series of four, 5 day courses:

- Theoretical foundations of sensory integration
- Technical and logistical administration of the SIPT as well as other commercially available measures of sensory processing
- Interpretation of the SIPT's standardized information and interfacing that information with other nonstandardized observations and

Sensory Integration and Praxis Test, Table 1 The 17 SIPT subtests

Test name	Description
Space Visualization	This test evaluates visual space perception and mental manipulation of objects in space. Motor performance is not required – therefore, deliberately visual and not visual-motor
Figure Ground	This test requires the child to select a foreground figure from a competing background
Standing and Walking Balance	This test evaluates the child's ability to balance on one or both feet, both statically and dynamically, with eyes open and closed
Design Copying	This section evaluates visuopractic and visuoconstruction skills. It assesses both accuracy and approach in copying designs
Postural Praxis	This part of the test evaluates the child's ability to imitate positions or postures demonstrated by the examiner
Bilateral Motor Coordination	This test measures the ability of the child to move both arms and both feet together in a smoothly integrated pattern
Praxis on Verbal Command	This test measures the child's ability to motor plan body postures from verbal directions without visual cues
Constructional Praxis	This test measures the child's ability to relate objects to each other in three-dimensional space. It involves visual spatial understanding and motor planning a course of action to replicate simple and complex block structures Constructional Praxis involves ideation, conceptualization, space perception, and planning
Postrotary Nystagmus	This test evaluates the integrity of a relatively discrete vestibular-ocular reflex following rotation. It is the only test of the SIPT that is reflexive rather than performance based
Motor Accuracy	This test is a visuomotor test which assesses eye-hand coordination in a wide variety of positions relative to the body, including crossing the body's midline
Sequencing Praxis	This test is designed to measure the child's ability to repeat a series of hand and finger movements following demonstration by the examiner
Oral Praxis	This test measures the child's ability to plan and execute tongue, jaw, and lip movements following demonstration by the examiner
Manual Form Perception	Part I – involves identifying the visual counterpart of a geometric form held and manipulated in the hand Part II – involves feeling a shape, without the aid of vision or visual cues with one hand and finding the matching shape among a line of blocks manipulated with the other hand, without the aid of vision and visual cues
Kinesthesia	This test assesses the capacity to perceive joint position and movement
Finger Identification	This test measures the ability to identify which finger or fingers are touched by the examiner with vision occluded
Graphesthesia	This test evaluates the ability to translate tactile input into a motor response. It assesses the integration between tactile and visual input and fine motor planning
Localization of Tactile Stimuli	This test assesses the child's ability to localize a specific tactile stimulus, applied to the hand or arm, with vision occluded

reports of the child's performance in order to develop appropriate intervention plans

- Intervention planning based on the theory of sensory integration, including practical applications and clinical reasoning strategies

Please note, however, that the USC/WPS website does not list therapists who were certified by the original organization sanctioned to offer the Certification of the Administration and Interpretation of the SIPT. As a result, parents and

professionals should not limit themselves to only those therapists registered with the USC/WPS organization.

Historical Background

The SIPT, years in development, was intended to help clinicians clinically understand the aspects of sensory processing and praxis abilities which contributed to irregularities in learning and behavior.

The theoretical model of sensory integration was the basis of the tool. This model highlighted how there are neurological processes which organize sensation from within one's own body and from the environment upon which an individual relies in order to use the body effectively to meet the demands of a given situation. It was theorized at the time that the body's receptors not only needed to accurately receive sensory stimuli but needed to efficiently process and organize this sensory information – i.e., select the needed information to make a response, inhibit information not needed, compare and synthesize the current information with past information stored within the brain, and relate the information to the current demand for action. The ability to flexibly and constantly perform this type of integration of information is necessary to perform functionally within an ever-changing environment. More specifically, the ability of a child to correctly receive, recognize, and integrate sensations from the body allows the child to “know” his/her body and develop plans for how to use the body for successful engagement in life's developmental tasks. When the child successfully plans and carries out an action, we call this action an “adaptive response” for a given situation or environmental demand.

The SIPT was designed to assess how the child perceives sensory information (tactile, proprioceptive/kinesthetic, vestibular, and visual) and how the body is able to plan or “do” requested motor actions.

Psychometric Data

In addition to the intent to create a reliable measurement and analysis of data by accepted statistical processes, the guiding principle in determining the procedures ultimately outlined in the SIPT was the “capacity of each measure to discriminate between dysfunctional and non-dysfunctional children of normal intelligence” (Ayres 1989, p. 161).

The standardization procedures began by ensuring a nationally representative sample based on the 1980 U.S. Census Bureau data,

including age, sex, ethnicity, rural/urban, and geographic location within the USA. Approximately 2,000 children were part of the standardization sample and testing occurred during the 1984–1985 school year. No children were included if there was an identified motor impairment (i.e., cerebral palsy) or severe visual handicap, and a number of children from Canada were included as it was expected that the tool would be utilized in that country.

Preliminary analyses examined age- and gender-related differences (multivariate analysis of variance [MANOVA]). Additionally, item data were examined to determine appropriate points to discontinue or stop the test without changing the outcome if the entire test had been completed (Pearson product-moment correlations and multiple discriminant analyses). Thereafter, statistical computation of group means and standard deviations was completed whereby separate norms were developed for each of the 12 age groups for girls and boys. Next, major SIPT scores were determined based on the extent by which they could discriminate between normal and dysfunctional performance.

A wide variety of studies were conducted to investigate construct, content, and criterion-related validity:

- Construct validity: the extent to which the test assesses the theoretical construct
- Content validity: the extent to which the test items provide a representative sampling of performance on important aspects of the construct
- Criterion-related validity: the extent to which performance on the test can be used to predict the child's current or future performance on important aspects of the construct (Ayres 1989, p. 181)

A detailed analysis of the SIPT's construct occurred via factor analyses (tests are grouped together with one underlying, common theme) and cluster analysis (children are grouped if they are alike). This initial information, as well as subsequent analyses, are presented in Table 2.

This information is important as the utility of a tool is whether the test can successfully and

Sensory Integration and Praxis Test, Table 2 SIPT factor and cluster analyses

Factor analyses (Ayres 1989)	Factor analysis (Mulligan 1998, p. 258)
• Bilateral integration and sequencing • Praxis on verbal command • Somatosensory and oral praxis • Visuopraxis • Somatopraxis	• Dyspraxia • Visual-perceptual deficit • Somatosensory deficit • Bilateral integration and sequencing deficit “Mulligan demonstrated that these four factors were highly correlated with one another, and proposed that they all relate to one underlying construct she names general praxis dysfunction.”
Cluster analyses (Ayres 1989)	Cluster analyses (Mulligan 2000, p. 258)
• Group 1: Low Average Bilateral Integration and Sequencing • Group 2: Generalized Sensory Integrative Dysfunction • Group 3: Visuo- and Somatodyspraxia • Group 4: Low Average Sensory Integration and Praxis • Group 5: Dyspraxia on Verbal Command • Group 6: High Average Sensory Integration and Praxis	• Cluster 1: Generalized Sensory Integration Dysfunction and Dyspraxia – Severe • Cluster 2: Dyspraxia • Cluster 3: Generalized Sensory Integration Dysfunction and Dyspraxia – Moderate • Cluster 4: Low Average Bilateral Integration and Sequencing • Cluster 5: Average Sensory Integration and Praxis

accurately identify clinically important groups of children who would be in need of different types of remediation or support.

Mulligan’s (1998) confirmatory factor analysis utilizing the SIPT scores of more than 10,000 children and cluster analyses (2000) provide clinicians with additional information useful in identifying deficits and planning interventions. Additionally, Davies and Tucker (2010) and Mailloux et al. (2011) provided additional perspectives on these analyses for practitioners to plan specific intervention strategies.

Clinical Uses

The SIPT is the only standardized assessment tool specifically designed to identify various types of sensory dysfunction. As stated above, however, sensory modulation issues are not specifically identified. As sensory modulation is an important component of sensory processing within the population of children identified as on the autism spectrum, other assessments might be more useful. Additionally, if the child to be evaluated is unable to follow only the stated directions or

attend for a long period of time, this assessment tool might not be appropriate.

Sensory Integration and Praxis Tests (SIPT)

► Touch Sensitivity

Sensory Overresponsivity as a Predictor of Amplitude Discrimination Performance in Youth with ASD

Elizabeth P. McKernan¹, Carissa J. Cascio² and Natalie Russo¹

¹Department of Psychology, Syracuse University, Syracuse, NY, USA

²Department of Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN, USA

Definition

The term “sensory overresponsivity” has been defined as an exaggerated, rapid-onset, or prolonged reaction to sensory stimulation (Ben-Sasson et al. 2008). It is estimated that 56 to 70 percent of youth with autism spectrum disorder (ASD) demonstrate sensory overresponsivity (Baranek et al. 2006). Sensory overresponsivity has also been associated with greater anxiety, social impairment, and functional impairment in individuals with ASD (Cascio et al. 2016; Green and Ben-Sasson 2010; Liss et al. 2006), making it a clinical construct of relevance for

this population. Though sensory overresponsivity has been documented in parent reports across the sensory modalities, atypical responses to touch are particularly highlighted in self- and parent reports and have been the focus of a substantive amount of experimental research (Cascio et al. 2012; Kaiser et al. 2015; Marco et al. 2012).

In particular, tactile processing in those with ASD has been investigated using psychophysical methods, which help to provide further insight into the neurobiological bases of sensory reactivity via objective, quantitative metrics. Tactile processing can be delineated into several components, including detection, discrimination, and adaptation. Tactile detection can be measured by flutter, vibration, and contact stimulation and indicates the point at which an individual is able to perceive the stimulus itself. Tactile discrimination refers to the ability to differentiate sensory information among various incoming stimuli. Finally, adaptation encompasses the impact of repetitive stimulation on a subsequent stimulus (Kohn 2007). Research with typically developing (TD) adults has indicated that the presence of an adapting stimulus increases the threshold for tactile discrimination of a subsequent stimulus (Tannan et al. 2008; Tommerdahl et al. 2010). That is, the adapting stimulus tends to reduce the perceived intensity of the later stimuli, making it more difficult to detect. Puts et al. (2014) investigated tactile processing using a tactile psychophysical battery in a group of TD children and children with ASD. Puts et al. (2014) found that performance on an amplitude discrimination task significantly worsened after single-site adaptation compared with a no-adaptation condition for TD children, whereas an increasing subthreshold stimulus did not have a significant effect on the performance of children with ASD on the same task. Such results imply that individuals with ASD demonstrate difficulties in their ability to habituate to incoming sensory information in comparison with TD individuals, such that they do not adjust as readily to prior sensory input.

Testing the effect of repetitive or long-duration stimuli on tactile processing thus provides a window into the ability to habituate to sensory information (Mikkelsen et al. 2018). Habituation is a

process by which repeated application of a stimulus results in a progressive decrease of a response over time. In general, habituation allows us to filter out irrelevant stimuli while focusing on important stimuli (Rankin et al. 2009). Several studies have suggested that habituation is reduced in individuals with autism (Guiraud et al. 2011; Kemner et al. 2002). In a study of habituation to repeated sounds in infants at high risk for autism, Guiraud et al. (2011) posited that reduced habituation may result in an inability to discriminate novel from repeated sounds, which may produce an increased response to repeated sensory input.

Given that a reduced ability to habituate may result in experiencing repeated sensory information as novel, this repeated stimulation may give rise to a behavioral experience of sensory overload. Consequently, it is possible that behavioral performance on tactile processing tasks is related to the construct of sensory overresponsivity. McKernan et al. (2019) used a set of amplitude discrimination tasks from the same tactile psychophysical battery as Puts et al. (2014) in a group of TD children and children with ASD. McKernan et al. (2019) found that sensory overresponsivity, as measured by caregiver report, predicted amplitude discrimination performance with an adapting stimulus as well as the effect of adaptation in the cohort of youth with ASD. It was also found that performance on the amplitude discrimination with adaptation task significantly predicted sensory overresponsivity scores among children with ASD, but not TD children, suggesting a bidirectional relationship between sensory overresponsivity and the effect of adaptation. Consequently, it is possible that sensory overresponsivity is the mechanism underlying the previously observed lack of an adaptation effect among children and adults with ASD.

Historical Background

Sensory sensitivities have long been reported in individuals with ASD, dating back to the 1940s with Leo Kanner's initial description of autism. Children, adolescents, and adults with ASD have been found to have significantly elevated levels of

sensory symptoms as compared to individuals with typical development and general developmental delay (Ben-Sasson et al. 2009; Failla et al. 2017; Rogers and Ozonoff 2005). Further, the severity of these sensory features is related to adaptive functioning among children with ASD (Rogers et al. 2003). Differences in sensory processing can be framed in terms of an increased or adverse response (hyperreactivity) or a decreased or lessened response (hyporeactivity) to sensory stimuli (Dunn and Brown 1997; Siper et al. 2017). Importantly, the degree and profile of sensory symptoms are highly varied in those with ASD (Cascio 2010), with many of these patterns co-occurring in the same individual, such that he or she may demonstrate hyporesponsivity in one sensory modality and hyperresponsivity in another (Ausderau et al. 2014; Iarocci and McDonald 2006; Lane et al. 2011). Sensory overresponsivity has been previously described as an exaggerated, rapid-onset, or prolonged reaction to sensation (Ben-Sasson et al. 2008), with behavioral features including avoidance of or prolonged negative responses to sensory stimuli (Liss et al. 2006). Traditionally, sensory overresponsivity has been measured by a combination of caregiver report (e.g., the Sensory Profile; Dunn 1999) and direct observation (Crane et al. 2009; Tavassoli et al. 2014; Wodka et al. 2016). In addition, specific measures of sensory overresponsivity have been developed, including the Sensory Overresponsivity Inventory (Schoen et al. 2008) and the Sensory Experience Questionnaire (Baranek et al. 2006). Importantly, however, questionnaire measures that assess sensory reactivity do not always converge with psychophysical thresholds indexing tactile sensitivity. In part, this may be due to the wide range of questions posed on questionnaire measures, many of which extend beyond the realm of pure sensory experience into perceptual, emotional, and cognitive responses associated with sensation. Conversely, psychophysical measures may provide a more specific measurement of individuals' behavioral responses to tactile input.

Use of psychophysical methods in the examination of tactile processing stems from the work of Weber and Fechner in the nineteenth century,

which gave rise to the investigation of detection thresholds and the just-noticeable difference. It is only in the last two decades, however, that psychophysical methods have been used to investigate tactile processing in individuals with ASD. A variety of metrics, including tactile detection thresholds, adaptation, and textures, have been used to expand inquiry yet have often produced conflicting results.

With regard to detection thresholds, a small body of literature has found no difference between adults with ASD and TD adults in contact detection threshold, as measured by Von Frey hairs (O’Riordan and Passetti 2006) and flutter stimulation (Blakemore et al. 2006), as well as children with and without ASD, as measured by flutter and vibration stimulation (Guclu et al. 2007). On the other hand, however, decreased flutter perception has also been reported (Puts et al. 2014; Tavassoli et al. 2016). It is likely that small sample sizes and differences in methodology contribute to the lack of clear conclusions in this regard (Mikkelsen et al. 2018). In addition, the large attentional demands inherent to such tasks make psychophysical studies more difficult, and consequently rarer, in samples of children.

In terms of behavioral response to textures, Cascio et al. (2016) investigated tactile defensiveness in children with typical development, ASD, and other developmental disabilities. Participants received passive touch from unpleasant, pleasant, and social textures (plastic mesh, soft fleece, and an experimenter’s finger, respectively) at three sites on the upper body. Children with ASD had significantly higher tactile defensiveness reactions and lower pleasantness ratings compared to the TD group, with the most pleasant material and the social touch conditions distinguishing the children with ASD and other developmental disabilities from TD children on tactile defensiveness. These results are in fitting with previous research with a group of adults with and without ASD by Cascio et al. (2012), which used functional magnetic resonance imaging (fMRI) to investigate responses to somatosensory stimulation with three textures spanning a range of roughness and pleasantness. Adults with ASD exhibited less activation in the primary somatosensory cortex for

neutral and pleasant stimuli but demonstrated greater response for unpleasant stimuli. Cascio et al. (2012) noted that these results point to the possibility of a predisposition to hyperresponsiveness to unpleasant tactile stimulation and hyporesponsiveness to positive or neutral tactile stimuli in those with ASD.

Current Knowledge

Across multiple studies, the effect of adaptation – presumed to be an increase or sharpening in contrast between stimuli – has been observed to be absent in both children and adults with ASD (Tommerdahl et al. 2007, 2008; Puts et al. 2014). A strong body of literature has proposed that GABA, an inhibitory neurotransmitter, may explain altered tactile processing in individuals with ASD. Indeed, previous research has found evidence for reduced GABA levels within sensory regions in children with ASD (Gaetz et al. 2014; Rojas et al. 2014). In addition to impairments in the inhibitory system in individuals with ASD, another potential contributor to the lack of an adaptation effect may be behavioral, as a result of overactive sensory responses.

McKernan et al. (2019) investigated the relationship between sensory overresponsivity, defined as an exaggerated response to sensory stimulation, and performance on three vibrotactile tasks: amplitude discrimination without adaptation at a single site, amplitude discrimination without adaptation at two sites, and amplitude discrimination with single-site adaptation. Participants included 25 TD children and 25 children with ASD between the ages of 6 and 17 years. Sensory overresponsivity was measured via a composite of items on the Sensory Profile, a caregiver questionnaire assessing children’s responses to various sensory experiences. The effect of adaptation was measured by the difference in performance on tasks with and without an adapting stimulus. Sensory overresponsivity did not significantly predict the difference on any of the amplitude discrimination tasks for TD youth. In contrast, sensory overresponsivity significantly predicted performance on the single-site

adaptation task, as well as the difference between adaptation and non-adaptation, for youth with ASD. The reverse relationships were also tested to determine whether performance on the amplitude discrimination tasks was predictive of sensory overresponsivity scores. None of the three tasks significantly predicted sensory overresponsivity in the TD group; however, the single-site adaptation task was found to significantly predict sensory overresponsivity in the ASD cohort. Taken together, these results imply that sensory overresponsivity has a unique and differential impact on tactile processing in children with ASD, such that the level of sensory overresponsivity may be a significant contributor to the reduction of adaptation effects among those with ASD.

Other research into the phenomenon of sensory overresponsivity has used neuroscience methods, such as fMRI, to investigate the brain's response to sensory stimulation. Green et al. (2019) exposed children and adolescents with ASD and typical development to two consecutive paradigms: an initial exposure phase, during which they experienced auditory, tactile, and joint (simultaneous auditory and tactile) stimulation, followed by a generalization phase, in which they experienced novel auditory, tactile, and joint stimulation. Tactile stimuli consisted of two scratchy sponges rubbed on participants' inner arms at a rate of one stroke per second. The ASD group was divided into youth with high and low levels of sensory overresponsivity. Green et al. (2019) found that participants with ASD in the high sensory overresponsivity group demonstrated a reduced ability to maintain habituation in the relevant sensory cortices and amygdala and to maintain inhibition in irrelevant sensory cortices. In this manner, it appears that children and adolescents with ASD with high levels of sensory overresponsivity were unable to maintain downregulation of brain responses across time and with a novel stimulus. Taken together, these results indicate that sensory habituation is a particular difficulty for those with ASD with high overresponsivity, which may also help to explain the lack of adaptation effect seen in previous psychophysics studies.

Future Directions

Although sensory overresponsivity has been shown to be predictive of performance on an amplitude discrimination task among children with ASD, its relationship to other tactile psychophysical tasks has yet to be investigated. As such, it is unknown which specific aspects of tactile processing are most associated with the construct of sensory overresponsivity and whether this relationship is unique to amplitude discrimination or is common among other psychophysical tasks. Further research regarding how these constructs relate across different sensory modalities, such as audition or vision, is also needed.

Previous research has also linked differences in tactile processing among individuals with ASD to altered GABA function in this population (Puts et al. 2011, 2017; Tavassoli et al. 2016). Much remains unknown regarding to what extent altered GABA functioning may explain the construct of sensory overresponsivity. Further exploration of this relationship may uncover a common mechanism responsible for observed differences in tactile processing among those with ASD.

Future research may also wish to consider the influence of sex differences upon the construct of sensory overresponsivity, as well as performance on tactile psychophysics tasks. Given the discrepancy in sex ratio in population estimates of ASD prevalence (Baio et al. 2018), many studies include a greater number of male than female participants. To date, no studies have explicitly examined the impact of sex differences on the relationship between sensory overresponsivity and the effect of adaptation. Further exploration into sex differences in sensory overresponsivity, as well as performance on tactile psychophysics tasks in general, is needed.

In addition, the measurement of the construct of sensory overresponsivity itself remains imperfect, as no one objective metric currently exists. The combination of caregiver and/or self-report measures of sensory processing, along with the use of a clinician-rated behavioral measure, may help to provide a thorough and more valid assessment of sensory overresponsivity; however, some degree of subjectivity is inherent in each of these

approaches. Innovative approaches, including the use of neuroscience methods such as fMRI, may provide an objectively empirical measurement of sensory overresponsivity.

Finally, given the substantial impact of sensory overresponsivity on quality of life, including symptoms of anxiety and functional impairment, in those with ASD (Green and Ben-Sasson 2010; Liss et al. 2006), future research would do well to develop and test specialized interventions related to sensory overresponsivity. Interventions may be at both an individual and a systems level, with a focus on increasing coping strategies in individuals with ASD who have high sensory overresponsivity, as well as modifying external home, school, and work environments to accommodate and support the needs of those with sensory processing differences. Distinctive interventions may be created for specific sensory modalities, in fitting with the heterogeneous profile of sensory processing differences among those with ASD. Such interventions will enable individuals with sensory overresponsivity and ASD to participate more fully in their communities, while respecting the unique way in which they perceive their sensory worlds.

Sensory Processing

Kristen M. Powers

Coordinator of Rehabilitative Services, Center for Children with Special Needs, Glastonbury, CT, USA

Definition

Sensory processing is a general term that describes the way that the central and peripheral nervous systems manage incoming sensory stimuli and allows for an organized and adaptive response to the presented sensory information (Lane et al. 2000). Through sensory registration,

the peripheral nervous system detects the input and relays the specific information to the brain. Sensory integration allows the organization of input from the different sensory systems to lead to an appropriate, adaptive response (Tomchek 2010). Sensory integration incorporates sensory modulation which allows us to notice important sensory information and to ignore irrelevant sensory stimuli. Deficits in sensory modulation may result in inattentiveness, sensory seeking behaviors, or avoidance of sensory input. Additionally, individuals with deficits in sensory modulation may also exhibit difficulty regulating their state of alertness and arousal, and fluctuations within these states may be evident. Maintaining a regulated emotional state may be challenging for some individuals with sensory processing deficits as well. Emotional lability may be noted or even a flattened affect. Adults with sensory processing difficulties may ultimately display sensory defensiveness as well as difficulties with discrimination, motor planning, and motor performance (May-Benson 2011).

Individuals with sensory processing deficits exhibit difficulty managing input from one or more of the sensory systems. The visual system within the context of sensory processing refers to the way the brain interprets visual information, separate from visual activity. Individuals with deficits in visual sensory processing may exhibit difficulty with distinguishing relevant visual information embedded in a rival background, such as reading from a chalkboard or whiteboard. Some individuals who may seek more intensive visual information may look at objects from an unusual perspectives or angles or engage in finger gazing.

Auditory (sensory) processing refers to the way in which the brain manages auditory stimuli, though separate from hearing. Individuals with deficits in auditory sensory processing may exhibit difficulty filtering out background noise while trying to listen to a classroom lecture. Exaggerated reactions to loud or unexpected noises may also be evident. Some individuals will cover their ears to such noises and may even avoid settings in which loud noises naturally occur. Other children with auditory sensory

processing difficulties may seek noises and may even engage in repetitive noise making to provide themselves with this type of input.

The olfactory and gustatory systems refer to the systems of taste and smell, respectively. Deficits in either one of these systems may affect food selectivity, an area of concern for some children with autism spectrum disorders. Some children may seek out intensive smells or tastes that are not typically part of a child's diet. Others may avoid smells or tastes that can limit an overall adequate food repertoire with a balanced diet. Some individuals may avoid environments that offer a distinct or unusual smell, ultimately impacting social participation if an individual avoids a cafeteria, restaurant, or family kitchen.

The tactile system refers to the sense of touch. Tactile perception allows us to have knowledge of tools and materials through touch alone. The sense of touch allows us to know where we were touched, an important component of maintaining social boundaries. Individuals who seek tactile stimuli may crave materials with a heightened or unusual texture or tactile surface. Some individuals may display inefficient tactile awareness and may ultimately exhibit difficulty with motor performance and tool usage. They may require visual support to assist with their performance. Individuals who are overreactive to tactile input may display exaggerated or heightened responses to tactile input and may avoid materials with an unusual tactile surface. These individuals may be extremely selective about what clothes to wear and having their hair combed or washed. Additionally, some individuals will avoid social situations in which unexpected touch opportunities may occur.

The vestibular system refers to the system of balance, reacting to head movement in relation to gravity. With head movement, eye, head, and postural reactions are integrated. Individuals who seek out vestibular input may crave more intensive movement opportunities, including spinning, rocking, and jumping. Some individuals may use repetitive rocking as a means of calming or self-regulation. Individuals who are hyper-responsive to vestibular input may dislike movement in which their heads are inverted, avoid swings, and get carsick easily. Some individuals

display gravitational insecurity in which they are uncomfortable if their feet leave the ground or their balance is displaced.

The proprioceptive system is triggered by movement or stretch and provides information on body-in-space awareness. Individuals with deficits in proprioceptive functioning may "crash" onto furniture or the floor, trail their hand along the walls and furniture as they are walking, or seek deep hugs. They might not notice if they are sitting too close to someone and may also exhibit grading motor force and pressure while performing motor actions. Their movements can be clumsy as they bump into furniture and objects in their environment. Individuals with deficits in proprioceptive functioning may use their vision as a means of providing increased feedback for body-in-space awareness and overall motor performance.

Overall motor planning and performance is dependent on adequate processing of sensory information and deficits in any of these areas can impact motor execution. Some children may display difficulty with motor imitation, tool usage, and overall initiation.

Historical Background

A. Jean Ayres, the clinician who first postulated sensory integration theory, described sensory and motor challenges in children with learning disabilities (Ayres 1963, 1965). Her early work expanded to identify different patterns of sensory integration dysfunction to conceptualize ways to understand sensory responses. Ultimately, sensory integration theory purports that motor performance, learning, and adaptive behavior are impacted by adequate processing and overall organization of sensory input (Baranek et al. 2008). Sensory integration therapy involves child-guided play addressing responsiveness to sensory input (Cascio 2010). Particular emphasis on tactile, vestibular, and proprioceptive input is incorporated into the interventions. Sensory integration therapy has been highly critiqued in the literature as an effective method of intervention (Hoehn and Baumeister 1994).

Current Knowledge

Further studies on sensory processing and how to conceptualize its influence on behavior continue to advance our understanding of this topic. Brown and Dunn (2010) outline four potential patterns of sensory processing based on Dunn's Model of Sensory Processing (Dunn 1997) that examines the relationship between neurological thresholds and behavioral responses. Dunn's model addresses a continuum and a level of interaction between the neurological thresholds and the behavioral responses as a way of understanding an individual's response to sensory information around them. The neurological thresholds are described as low or high, and the following four patterns of behavioral responses are identified: registration, seeking, sensitivity, and avoiding. *Registration* refers to the extent to which an individual misses sensory information. *Seeking* refers to the extent that an individual acquires sensory information. *Sensitivity* refers to the degree that an individual is aware of sensory information, and *avoiding* refers to the degrees by which an individual is bothered by sensory information.

Some individuals with a high neurological threshold may crave more intensive sensory experiences and may look to such heightened sensory input as frequent movement experiences to satisfy their need to acquire sensory input. These individuals may be perceived as risk taker or impulsive with poor personal boundaries. Some individuals with hyporesponsiveness may display sluggish or delayed reactions to sensory input. These individuals may exhibit difficulty recognizing or attending to sensory input in their environment and ultimately exhibit a more passive or even delayed response. Some individuals may use visual feedback to provide themselves with increased body-in-space awareness or may even engage in self-stimulatory behaviors to provide themselves with increased input.

Children and adults with a low neurological threshold may exhibit hyperresponsive reactions to sensory information and may display exaggerated and prolonged responses to sensory stimuli. Individuals may learn to avoid situations that provide sensory input that may be perceived as

unpleasant or display unusual responses to these types of sensory input. Engaging in repetitive actions may be evident and used as a means of calming an overaroused nervous system. Fluctuations in alertness and arousal may also be noted, impacting focus and attention and even general social interactions. Ayres (1972) described fight-flight-or-fright responses to sensory input as well, resulting in exaggerated responses to sensory stimuli, freezing in place to a specific sensory trigger with delayed responses, or even aggressive behaviors in the presence of sensory input.

Sensory processing is addressed by many different disciplines as difficulties in this area can manifest itself in different domains, including social participation, learning, play, and activities of daily living. Occupational therapists, physical therapists, speech and language pathologists, social workers, psychologists, and physicians may all work together to facilitate the child's performance in a variety of environments for successful participation. Environmental modifications may be necessary to promote participation in different settings, including headphones for a loud cafeteria or a study carrel in a visually stimulating classroom.

While environmental modifications and activity adaptations offer a way to facilitate participation for those individuals who demonstrate deficits in sensory processing, some clinicians address changes within the individual child. Sensory integration is based on the premise that activities that offer needed sensory stimulation will promote the brain's ability to process sensory information more effectively (Ayres 1972, 1979). Lane and Schaaf (2010) examined neuroplasticity and found that sensory input, motor performance, and motivation all affect neuroplasticity and subsequently support occupational therapy/sensory integration interventions.

Future Directions

Continued focus on evidence-based practice has prompted practitioners seek to demonstrate the overall effectiveness of interventions for sensory processing difficulties, particularly in regard to

sensory integration therapy. Psychophysical, neuroanatomical, and neurophysical measures have yielded much information on somatosensory processing (Cascio 2010) and may provide additional methods of effective intervention strategies, particularly in relation to tactile deficits. Miller et al. (2007) noted a reduction in the amplitude of electrodermal responses to sensory stimuli for children with sensory modulation disorders when a sensory integrative approach was incorporated into occupational therapy intervention. There is general agreement that the interventions aimed at sensory processing require further examination and research (Baranek 2002) and may ultimately show positive effects (Benson and Koomar 2010). Efforts to investigate empirically those specific sensory intervention procedures used with those with autism (e.g., weighted vests) and those used as part of multielement component interventions (e.g., brushing program) will continue to shed light on both the process of intervention and the potential outcomes that are predicted by those treatments. Additional work investigating the functional relationship between particular sensory deficits and the prediction and attainment of specific outcomes will also support the evidence-based use of these procedures.

Description

The *Sensory Processing Assessment* (Baranek 2010), currently in revision/development, is an observational assessment which provides objective data regarding a “child’s approach, avoidance, and/or seeking behaviors with novel sensory toys, orienting and habituation responses to social and non-social sensory stimuli, and generation of novel action strategies with toys” (p. 2). This 15-min, play-based tool is currently being utilized in several research projects but is not yet published in final format. The design, for children between 9 months and 6 years of age, was intended for use with children on the autism spectrum and other developmental delays to assist with identifying patterns of sensory processing. It was thought that this tool could be utilized as a counterpart of the Sensory Experiences Questionnaire (SEQ; refer to the “[See Also](#)” section below) which is a parent report assessment tool.

There are four parts to this assessment tool with identified descriptors as to what the examiner should observe in order for the child to obtain a specific score:

- Novel Sensory Toys – rates hyper-responsiveness and sensory seeking
- Sensory Habituation – observes responses to repeated stimuli
- Sensory Orienting Trials – rates hyporesponsiveness
- Stereotyped Behaviors Checklist – items marked as observed or not

Historical Background

The author, Grace Baranek, Professor and Associate Chair of Research at the University of North Carolina – Chapel Hill’s Division of Occupational Science and Occupational Therapy, has a long-standing and very well-respected history of research in the area of autism spectrum disorders. The Sensory Experiences Project (SEP), funded by the National Institute for Child Health and Human Development, focuses on the research on the sensory features/processes of children on the autism spectrum, developmental delay, and/or typical development for children 2 through 12 years old. This research is conducted under the University’s PEARLS project (Program for Early Autism Research, Leadership, and Service) whose intent is improve early identification markers and contribute to the evidence with regard to best practices in intervention.

Psychometric Data

Preliminary studies of reliability and validity have been completed. As this assessment tool is not yet published, full detail of the psychometric data is not yet available.

Clinical Uses

The intended use of this assessment tool is to augment traditional diagnostic and developmental

assessment in order to identify patterns of sensory processing which may have implications for diagnosis or intervention. As this tool is not yet published, a full description of its clinical use is not yet available.

Description

The *Sensory Processing Measure* (SPM) is a standardized assessment tool published by Western Psychological Services (www.wpspublish.com) that provides information about the sensory and environmental issues that may impact a child's performance in school, home, and community settings (Parham et al. 2007). The design of the SPM allows a practitioner to consider whether a child's performance is being hindered by sensory processing or sensory integration difficulties. The SPM's three integrated rating scales (Home Form, Main Classroom Form, and School Environments Form) are designed to elicit information about the sensory processing, praxis, and social participation of primary school children ages 5–12 years (Miller Kuhaneck et al. 2007a, b; Parham and Ecker 2007). With the SPM in part being grounded in Ayres Sensory Integration (SI) theory (Ayres 1972, 1979, 2005), it provides norm-referenced standard scores for two higher

level integrative functions (praxis and social participation) and five sensory systems; those being visual, auditory, tactile, proprioceptive, and vestibular functioning (see Table 1) (Parham et al. 2007). Within each sensory system, the SPM offers clinical information on a number of processing SI vulnerabilities including under-responsiveness, over-responsiveness, sensory-seeking behavior, and perceptual problems (Parham et al. 2007).

The SPM Home Form (made up of 75 items) (Parham and Ecker 2007) is completed by a child's parent or caregiver while the SPM Main

Classroom Form (consisting of 62 items) (Miller Kuhaneck et al. 2007a) is filled out by a child's main classroom teacher (see Table 1). The SPM School Environments Form (containing 10–15 items per school environment) (Miller Kuhaneck et al. 2007b) is completed by other school staff who work with and know a child in those relevant school contexts (e.g., school bus driver, physical education teacher, librarian). The SPM Home and Main Classroom Forms each take approximately 15–20 min to be completed by respondents and about 5–10 min to be scored by practitioners (Parham et al. 2007). The SPM forms are written at an 8th grade reading level, but in the event that parents have poor reading skills, it is possible to complete the Home Form by interviewing the respondent(s).

All forms of the SPM have items that are answered by respondents using a 4-point Likert-type scale (Never = 4, Occasionally = 3, Frequently = 2, Always = 1) (Parham et al. 2007). The SPM AutoScore™ feature (forms containing a sheet of carbon paper) permits the transfer of respondents' answers to a scoring worksheet that allows for easy calculation of the subscale scores. The clinician adds up and transfers the raw subscale scores to the SPM Profile Sheet. Prior to giving the SPM AutoScore™ proforma to the parent or teacher, the Profile Sheet must be detached so that it can be used later in scoring the scale.

The eight sensory processing scores (Social Participation [SOC], Vision [VIS], Hearing [HEA], Touch [TOU], Body Awareness [BOD] (proprioception), Balance and Motion [BAL] (vestibular function), Planning and Ideas [PLA] (praxis), and Total Sensory Systems [TOT]) generated by both the SPM Home and Main Classroom Forms are converted from raw scores into T-scores as well as their corresponding percentile ranks (Miller Kuhaneck et al. 2007a; Parham and Ecker 2007). The T-scores for these two forms are then identified for interpretive purposes as falling into one of three categories: the *Typical* range (T-score of 40–59 indicating a child's behavioral and sensory functioning are similar to that of typically developing peers), the *Some Problems* range (T-score of 60–69 indicating that a child

Sensory Processing Measure, Table 1 Sensory Processing Measure (SPM) forms and scales

School bus (BUS)	10

Note: The SPM Home and Main Classroom scales yield norm-referenced standard scores. The SPM School Environments scales yield Total Scores that are interpreted by means of a cutoff criterion. The TOT scales include VIS, HEA, TOU, BOD, and BAL items, plus several items representing taste and smell processing
Source: Parham et al. (2007, p. 4). (Reproduced with permission from publisher)

exhibits mild-to-moderate difficulties in his or her behavioral or sensory functioning), or the *Definite Dysfunction* range (T-score of 70–80 indicating that a child is presenting with significant sensory processing problems that are likely having an impact on his/her daily functioning) (Miller Kuhaneck et al. 2007a; Parham and Ecker 2007).

“The VIS, HEA, TOU, BOD, and BAL scales are referred to as the *sensory systems scales* because they address a child’s ability to process direct sensory inputs. The SOC and PLA scales, on the other hand, represent higher level integration functions that are strongly influenced by sensory inputs while encompassing other cognitive and contextual factors. The TOT scale is a composite of all the sensory system scales, plus additional items that reflect taste and smell inputs” (Parham et al. 2007, p. 19). One advantage of using the SPM is that for the first time, an Environment Difference score permits direct comparison of a child’s sensory functioning at home and at school. While the scales on the SPM Home and Main Classroom Forms are identical, the items themselves are specific to each specific environment. Individual item responses indicate how sensory difficulties present themselves in these two different settings.

With the SPM, the School Environments Form is provided on an unlimited-use CD. This allows the SPM user to look at the child’s functioning in six specific school environments outside of the main classroom: Art Class (ART), Music Class (MUS), Physical Education Class (PHY), Recess/Playground (REC), Cafeteria (CAF), and School Bus (BUS) (see Table 1) (Miller Kuhaneck et al. 2007b). Each school environment has its own Rating Sheet, which can be printed from the CD provided with the purchase of a test manual (Miller Kuhaneck et al. 2007b). Each rater can complete his or her 15-item Rating Sheet (10 items for the School Bus setting) in less than 5 min.

The SPM School Environments Forms yield no T-scores. Instead, these forms yield a total score for each relevant school environment that is interpreted against an established cutoff criterion. Scores at or above the cutoff point indicate that the child is experiencing a high number of sensory processing problems in that specific

school environment (Miller Kuhaneck et al. 2007b). Whether a practitioner uses one or all six Rating Sheets, the SPM School Environments Form must always be administered in conjunction with the SPM Main Classroom Form (Parham et al. 2007). In other words, the SPM School Environments Form should not be used in isolation. As reported in the SPM manual, the SPM School Environments Form items include behavioral indicators of sensory modulation dysfunction, difficulties with regulation of arousal, and praxis deficits that may be influencing educational performance, as well as the ability to participate fully in the educational environment and maintain relationships with peers (Miller Kuhaneck et al. 2007b).

Historical Background

The SPM came about with the cooperation of two groups of occupational therapy researchers in the United States who were each completing separate studies with the goal of generating a scale that would provide a link between home and school environments in the identification of SI problems. The SPM Home Form originated from the *Evaluation of Sensory Processing* by Parham and Ecker (2002), while the SPM Main Classroom and School Environments Form evolved from the *School Assessment of Sensory Integration* by Miller Kuhaneck et al. (2007a). “The goals underlying this combination of assessment instruments were to maximize the clinical utility of the measures and share a common standardization effort. By so doing, it was the test authors’ intent to create an integrated collection of parallel test materials regarding sensory processing and sensory integration that could be used across multiple settings” (Watson and Woodin 2007, p. 3). The test authors set out to reformat the scales so that they were more efficient and user friendly. A research version of each instrument was created to be used in the standardization of the SPM.

The theoretical basis of the SPM was derived from Ayres’s theory of SI (Ayres 1972). The SPM manual reports that disorders of SI are believed to

include the following: not using sensory information, sensory-seeking behaviors, being overwhelmed by sensory stimuli, difficulties with sensory discrimination, and sensorimotor problems. It is suggested that children who exhibit impediments with sensory processing may have difficulties in other areas of functioning such as planning and organizing their body movements.

Psychometric Data

Given that the SPM is a relatively new scale, limited psychometric data has been reported about it by external researchers and reviewers (Brown et al. 2010; Henry 2007; Henry et al. 2009; Kuhaneck and Henry 2009a, b). The information reported in this section focuses on the recent reliability and validity data reported in the SPM manual published in 2007 (Parham et al. 2007). The SPM Home Form and Main Classroom Form were standardized on a sample of 1,051 typically developing children ages 5–12 years in kindergarten through to grade 6 from approximately 76 sites across the United States (Henry 2007). All of the children in the sample were assessed with the SPM Home Form (completed by the child's parent or caretaker) and Main Classroom Form (completed by the child's primary school teacher). No children included in the standardization sample were attending full-time special education programs; however, "no attempt was made to exclude children with mild academic or behavioral difficulties" (Parham et al. 2007, p. 47).

Demographic data about the standardization sample were compared by age and against the 2001 American Census population estimates with regard to gender, race, geographical distribution, and educational attainment of parents (Henry 2007). In the SPM manual, it was noted that "whites are slightly overrepresented, whereas Blacks and Asians are slightly underrepresented. . . in terms of U. S. geographical distribution, the Midwest is overrepresented compared to Census figures, whereas the South and West are underrepresented" (Parham et al. 2007, p. 47). A subsample of 306 children from the SPM

standardization sample was used to develop scores for the School Environments Form (Miller Kuhaneck et al. 2007b).

Types of reliability data often reported include internal consistency, test-retest/time sampling reliability/temporal stability, inter-rater/inter-scorer reliability, intra-rater/intra-scorer reliability, alternate form reliability, and split-half reliability (American Educational Research Association [AERA], American Psychological Association [APA] and National Council on Measurement in Education [NCME] 1999). For the SPM Home Form subscale scores, internal consistency Cronbach alpha coefficients ranged from 0.77 to 0.95 (median = 0.85), while for the SPM Main Classroom Form subscale scores, internal consistency Cronbach alphas ranged from 0.75 to 0.95 (median = 0.86) (Parham et al. 2007). The SPM VIS, HEA, and TOU subscales had the lowest internal consistency estimates ranging from 0.75 to 0.84 for the total sample. "Although acceptable, this is concerning as vision, hearing and touch would be areas where the identification of sensory issues would be most observable. Social Participation, Planning and Ideas, and the Total Sensory Systems Score all demonstrate excellent reliability" (Cruce 2007, p. 2). The SPM School Environments scores yielded internal consistency values that ranged from 0.82 to 0.91 (median = 0.89) (Parham et al. 2007). "Internal consistency for the School Environments Form also was strong" (Cruce 2007, p. 2).

Test-retest reliability data were collected on 77 children ages 5–12 in a 2-week follow-up using both the SPM Home and Main Classroom Forms. As would be expected, temporal stability was high with all composites having correlation coefficients above 0.94 (Cruce 2007). For the SPM Home Form subscale scores, test-retest reliability coefficients ranged from 0.94 to 0.98 (median = 0.97), while for the SPM Main Classroom Form subscale scores, test-retest reliability coefficients ranged from 0.95 to 0.98 (median = 0.97) (Parham et al. 2007). "Additionally, standard errors of measurement and confidence intervals calculated at 95% appear to be quite acceptable" (Cruce 2007, p. 2).

Types of validity often reported for tests include face validity, content validity, criterion-related validity, and construct validity (AERA, APA, & NCME 1999; Anastasi and Urbina 1997). Two subtypes of criterion-related validity frequently included are concurrent validity and predictive validity, while subtypes of construct validity often reported include factor analysis validity, discriminant validity, convergent validity, divergent validity, diagnostic validity, and rating scale validity (Fawcett 2007; Wolfe and Smith 2007a). Many scales are now using a combination of Classical Test Theory methods (e.g., factor analysis) and Item Response Theory approaches (e.g., Rasch analysis) to examine the construct validity of a measure (Wolfe and Smith 2007b).

Limited evidence of validity was reported in the SPM manual. Content validity for the SPM forms was initially examined using the *Evaluation of Sensory Processing* (Johnson-Ecker and Parham 2000; Parham and Ecker 2002) and the *School Assessment of Sensory Integration* (Miller Kuhaneck et al. 2007a, b, c) in their original form. The items from the two original scales were examined and those items that were redundant or not aligned with Ayres's SI theory (Ayres 1972, 1979) were discarded. The item sets were then subjected to several rounds of expert review and were retained only if they were judged to adequately represent the intended sensory function construct, social participation, or praxis (Parham et al. 2007). "These earlier developmental phases generate confidence in the content validity of the current SPM items and scales" (Parham et al. 2007, p. 57).

A research version of the SPM was subjected to confirmatory and exploratory factor analyses to examine its construct validity. "Results of the factor analyses provided support for the basic scale structure of the SPM" (Watson and Woodin 2007, p. 3). Item-scale correlations are reported for the Home Form and the Main Classroom Form. According to Watson and Woodin (2007), the item-scale correlations provide "robust support for the Home Form as a measure that can be scored and interpreted according to its separate scales. In contrast, questionable results were

attained for the Main Classroom Form in terms of high interscale correlations between the BOD (proprioception) and BAL (vestibular) scales. This finding should be considered when interpreting results from these scales in individual cases" (p. 3). The standard errors of measurement varied between 1.29 and 4.40 points (Parham et al. 2007).

Convergent validity (a subtype of construct validity) was examined by comparing the SPM to the Sensory Profile (Dunn 1999), and the results indicated adequate overlap in areas where the tests displayed similar content. "Findings indicated that the SPM Home Form yielded strong and consistent relationships with the scores on the Sensory Profile" (Watson and Woodin 2007, p. 3). No comparable measure was available to investigate the convergent validity of the SPM Main Classroom Form. Therefore, the relationship between the SPM Main Classroom Form and the independently completed SPM School Environments Forms was examined. "Findings of strong relationships between these forms provide support for the stability of measurement of these forms" (Watson and Woodin 2007, p. 3). Brown et al. (2010) examined the convergent validity between the Home and Main Classroom Forms SPM and the Sensory Profile School Companion. The Sensory Profile and the SPM Home Form were significantly correlated ($\rho = 0.86$, $p < 0.01$). The Sensory Profile School Companion and SPM Main Classroom Form were also significantly correlated ($\rho = 0.74$, $p < 0.01$). The authors concluded that the two sensory processing scales exhibited moderate levels of convergent validity.

Discriminant validity (a subtype of construct validity) was evidenced by the SPM's ability to differentiate between two groups of children with known differences, those with typical development from those with formally diagnosed clinical disorders. It was reported in the SPM manual that a sample of 345 children (separate from the standardization sample) receiving occupational therapy intervention was used to verify that the SPM subscales were able to differentiate between typical children from those with clinical disorders (Parham et al. 2007).

The SPM authors used Rasch analysis (Bond and Fox 2001) to investigate its rating scale validity structure. With Rasch analysis, two sets of scores are generated, one for children (person ability scores) and the other for the SPM items (item difficulty scores), expressed by means of a common numerical metric called a logit score (Bond and Fox 2001). The use of a common logit allows instrument developers to examine the functioning of items with respect to different ability levels of participants. In other words, “the Rasch method illuminates how the categories of the SPM item rating scale operate together to measure vary amounts of sensory processing dysfunction” (Parham et al. 2007, p. 69). The rating scale validity results indicated that each of the SPM’s four rating scale categories (Never, Occasionally, Frequently, Always) “is the most probable response for a distinct level of the underlying sensory processing dysfunction. . .none of the categories are redundant. . .the category sequence of increasing behavioral frequency is properly aligned with the continuum of increasing sensory pathology” (Parham et al. 2007, p. 69).

Parham et al. (2007) investigated the moderating effects of demographic variables (including age, gender, ethnicity, and socioeconomic status [SES]) on the SPM scale scores. “An effect size metric was used to determine if the demographic moderator variables were associated with any clinically meaningful differences between groups in the SPM raw scale scores” (Parham et al. 2007, p. 47). The analysis of the demographic moderating effects did not yield any significant results. “Actual differences in SPM scores due to age, gender, ethnicity, and SES were small and not likely to have any meaningful impact on interpretation of [SPM] test results” (Parham et al. 2007, p. 49).

Lai et al. (2011) explored the psychometric properties of a Chinese version of the SPM referred to as the Sensory Processing Measure-HK Chinese (SPM-KHC). The original SPM Home Form and Main Classroom Forms were translated into Chinese using the forward and backward translation procedure. The equivalence of the translation was reviewed by a panel of eight experts and content validity (relevance and

representativeness) was assessed by a panel of 20 experts. Data was collected from two groups of participants: a group of typically developing children and a group of children presenting with ASD. The sample sizes were as follows: 542 healthy children for the SPM Home Form, 325 healthy children for the SPM Main Classroom Form, 100 children with ASD for the SPM Home Form, and 95 children with ASD for the Main Classroom Form (Lai et al. 2011). The internal consistency coefficients for the SPM-KHC Home Form scales ranged from 0.674 to 0.861 and from 0.779 to 0.933 for the SPM-KHC Main Classroom Form. Two week test-retest ICCs for the SPM-KHC Home Form ranged from 0.70 to 0.95 and from 0.82 to 0.97 for the SPM-KHC Main Classroom Form (Lai et al. 2011).

Convergent validity between the SPM-KHC Home Form and the Chinese Sensory Profile in the form of correlations between the scales of the instruments ranged from -0.357 to -0.673 (Lai et al. 2011). The SPM-KHC Home Form and the SPM-KHC Main Classroom Form subscales were able to discriminate between the two participant groups thus providing evidence of its discriminant validity. The construct validity of the SPM-KHC is examined by exploratory factor analysis. For the SPM-KHC Home Form, “principal component analysis extracted 22 factors with eigenvalue greater than 1” that accounted for 61.4% of the total variance (Lai et al. 2011, p. 2640). For the SPM-KHC Main Classroom Form, “principal component analysis extracted 12 factors with eigenvalue greater than 1” that accounted for 67.3% of the total variance (Lai et al. 2011, p. 2640). For both the SPM-KHC Home and Main Classroom Forms, the first factor included all the items of Vision, Hearing, Touch, Taste and Smell, Body Awareness, Balance and Motion, and Planning and Ideas scales.

Clinical Uses

As outlined in the SPM manual, it has three primary uses: (1) providing clinicians with information regarding a child’s sensory integrative functioning in order to create strategies that

enhance performance in school and at home; (2) evaluating a child's performance in a variety of different environments, allowing comparison and discussion regarding the differences; and (3) examining the behaviors indicative of sensory modulation dysfunction and dyspraxia, as well as the related areas of arousal, attention, and social participation (Parham et al. 2007). Watson and Woodin (2007) state that "the SPM will be useful in determining the types of interventions that would be most appropriate for a child as a means of measuring program effectiveness, building team collaboration regarding intervention strategies, fostering program planning, and developing Individualized Educational Plans (IEPs)" (p. 3). In summary, the SPM scales can be used in a range of educational, clinical practice, and research settings.

Dr. Ayres (1972, 1979) first coined the term *sensory integration dysfunction* as part of her theory that deficits in processing sensation from the body and the environment lead to sensorimotor and learning problems in children. More recently, the term *sensory processing disorder* (SPD) has been proposed. It is estimated that SPD affects the lives of 1 in 20 children and adults (Ahn et al. 2004). SPD is recognized by both the *Diagnostic Manual for Infancy and Early Childhood* (DMIC) of the Interdisciplinary Council on Developmental and Learning Disorders (2005) and the *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood, Revised* (DC:0-3R) (Zero to Three 2005). Three primary diagnostic groups have been categorized within the SPD category to describe children who have difficulty regulating and organizing responses to sensory input: *sensory modulation disorder*, *sensory discrimination disorder*, and *sensory-based motor disorder* (Ayres 2005; Miller et al. 2007; Miller Kuhaneck et al. 2010).

Sensory modulation disorder has three subtypes: *sensory over-responsivity*, *sensory under-responsivity*, and *sensory seeking* (Roley et al. 2001; Dunn 2010). Children with *sensory over-responsivity* register sensations too intensely and for a longer duration than typically developing children and may react to sensory input by pulling

away, screaming, or avoiding input (Robinson and Magill-Evans 2009). Children with *sensory under-responsivity* tend not to respond to input and may be withdrawn or seem to be in their own world (Dunn 2010). *Sensory seeking* describes children who tend to crave intense or an unusual amount of sensory input. They may be constantly on the move, bang their heads against windows or walls, or fall repeatedly in an effort to gain appropriate sensory information (Miller Kuhaneck et al. 2010). The other two diagnostic groups include sensory discrimination disorder or difficulty deciphering or interpreting qualities of sensory information and sensory-based motor disorder, in which children tend to appear uncoordinated because of faulty processing of sensory input (Dunn 2010). A diagnosis of SPD is not made unless the condition significantly affects a child's daily life (Baranek et al. 2006).

The SPM forms can be used by a variety of health and education professionals (including occupational therapists, psychologists, teachers, social workers, counsellors, physiotherapists, speech-language pathologists, nurses, pediatricians, and physicians, among others) to evaluate the sensory processing issues of school-age children (Henry et al. 2009). For example, the SPM's unique multi-environment approach let practitioners investigate why a child who functions well in a highly structured classroom with a predictable daily routine may have problems at home or at a playground in the local community park where the environment is variable and the routine is not predictable. Cruce (2007) states that the SPM is "a good choice if one needs to identify sensory difficulties across environments, and the School Environments Form especially fills a gap seen in most rating scales as it looks at alternate settings where students are likely to struggle. This measure is best used comprehensively, and one should be guarded in interpreting the SPM Main Classroom Form in isolation without the use of the SPM Home Form for comparison" (p. 3).

The SPM can be used to determine whether a child is presenting with signs indicative of SPD. One study by the Sensory Processing Disorder Scientific Work Group (Ben-Sasson et al. 2009)

suggests that one in every six children experiences sensory symptoms that may be significant enough to have a negative impact on some aspect of everyday life functions. A significant number of children diagnosed with autism spectrum disorder (ASD) (and related disorders) present with signs of SPD (e.g., child who does not like to eat foods with certain textures or smells, does not like to wear clothes made of certain types of material, does not like to wear socks or shoes, does not like to be hugged, does not like to handle certain types of materials such as Playdoh™, and/or does not like having his or her hair brushed or washed) (Baranek et al. 2005; Kientz and Dunn 1997; Leekam et al. 2007; Tomchek and Dunn 2007; Watling 2000; Watling et al. 2001), and the SPD would be a measure suitable to assess this group of children. “Children with autism are expected to show elevated scores on the SPM SOC and PLA scales. . .these deficits in participation and praxis may be caused or exacerbated by processing deficits in specific sensory systems” (Parham et al. 2007, p. 33). Parham et al. also noted that “with moderate to severe autism, it is not uncommon to see all SPM scales elevated in the Definite Dysfunction range” (p. 33).

The SPM can be used to assess children presenting with suspected sensory processing challenges as well as children with confirmed diagnoses including genetic disorders, developmental disabilities, learning disabilities, neurological problems, behavioral issues, or psychosocial problems (Baker et al. 2008; Carrasco Koester et al. 2014; Hansen and Jirikowic 2013; Pfeiffer et al. 2015; Robinson and Magill-Evans 2009; Rosenberg et al. 2015; Spira 2014). It states in the SPM manual that it was not designed for use with students with severe sensory impairments such as blindness or deafness or children with severe motor impairments (Parham et al. 2007). It can be used in conjunction with other assessment tools to provide a comprehensive overview of a child’s daily functioning or can be used as a stand-alone tool. Similarly, the SPM can be used to document children’s progress or clinical change after being involved in an intervention program (e.g., pre-intervention and posttest intervention). Recently a number of studies have been published

where the SPM has been used to assess the sensory processing issues of children presenting with ASD (Chang et al. 2012; Fernández-Andrés et al. 2015; Gee et al. 2014; Gibbs and Toth-Cohen 2011; Sanz-Cervera et al. 2015; Smith Roley et al. 2015).

Cruce (2007) noted that “the SPM appears to be a usable, structurally sound instrument that attempts to quantify sensory problems in children. The SPM would be a good instrument for occupational therapists to use in planning appropriate empirically validated treatment options” (p. 3). In conclusion, the SPM appears to be a useful, informative, and psychometrically sound scale that clinicians can use with confidence to assess school-age children including those diagnosed with ASD. Watson and Woodin (2007) stated that the “SPM has an adequate normative base, provides data across multiple settings in home and school environments, is easy to administer and score, and provides adequate to moderate evidence of reliability, validity, factor structure, and discriminant validity” (p. 3).

Sensory Processing Measure: Preschool (SPM-P)

Ted Brown

School of Primary and Allied Health Care,
Faculty of Medicine, Nursing and Health
Sciences, Monash University – Peninsula
Campus, Frankston, VIC, Australia

Abbreviations

ASD	Autism spectrum disorder
BAL	Balance and motion
BOD	Body awareness
DIF	Environment Difference Early
ECIS	Childhood Intervention Service
HEA	Hearing Infant Toddler Sensory
IFSP	Profile
PLA SD	Planning and Ideas Standard Deviation
SI	Sensory integration
SOC	Social participation
SPD	Sensory processing disorder
TOT	Total sensory systems
TOU	Touch
VIS	Vision

Synonyms

[Sensory processing measure; SPM; SPM-P](#)

Description

The *Sensory Processing Measure – Preschool* (SPM-P) (Glennon et al. 2011; Miller Kuhaneck et al. 2010a, 2010b) is a set of scales that allows the assessment of praxis, social participation, and

sensory processing issues present in preschool-age children (2–5 years of age). The SPM-P consists of the Home Form (Ecker and Parham 2010) and the School Form (Miller Kuhaneck et al. 2010) that are published Western Psychological Services (www.wpspublish.com). The SPM-P is a companion instrument to the *Sensory Processing Measure* (SPM) (Parham et al. 2007) that is designed for use with children ages 5–12 years. The SPM-P has the same theoretical basis and subscale structure as the SPM. “These commonalities facilitate a seamless transition between the two assessments for children who need to be followed over the longer term” (Miller Kuhaneck et al. 2010, p. 3). It should be noted that the coverage of 5-year-olds is common to both the SPM and SPM-P; for 5-year-olds who have not yet started kindergarten, then the SPM-P should be used, whereas the SPM should be utilized for 5-year-olds who have already enrolled in kindergarten/grade one.

Similar to the SPM, the SPM-P is contextualized within Ayres sensory integration (SI) theory (Ayres 1972, 1979, 2005). “The theory holds that children with compromised sensory processing may be unable to learn efficiently, regulate their emotions, or function at an expected level in daily activities” (Miller Kuhaneck et al. 2010, p. 3). As well, sensory processing problems lead to difficulties in higher level integrative functions, such as praxis (the ability to plan and organize movement) and social participation (Dunn 2010). Ayres SI theory outlines assessment principles related to sensory function, three of which are incorporated into the SPM-P: (1) it includes *assessment of sensory systems* since it includes subscales that examine the tactile, visual, auditory, proprioceptive, and vestibular sensory systems; (2) it incorporates *assessment of sensory integration vulnerabilities* by providing information about the weaknesses in each sensory system including under-responsiveness, over-responsiveness, sensory-seeking behavior, and perceptual problems; and (3) it allows *assessment across multiple environments* since the clinician can compare a child’s sensory processing functioning across the home, preschool, and community contexts (Miller Kuhaneck et al. 2010).

The SPM-P Home Form consists of 75 items designed to be completed by a child’s parent or caregiver. The SPM-P School Form also contains 75 items meant to be completed by a child’s preschool teacher or child care provider. According to the SPM-P manual, a respondent “must have observed the child in the preschool or day care setting on a daily basis for at least 1 month prior to completing the School Form” (Miller Kuhaneck et al. 2010, p. 5). Both forms take approximately 15–20 min to complete and 5–10 min to score. The SPM-P forms are written at an 8th grade reading level, but in the event that parents have poor reading skills (e.g., English as a second language), it is possible to complete the Home Form by interviewing the respondent(s).

The SPM-P Home and School Forms have items that are answered by respondents using a 4-point Likert-type scale based on the frequency of a specific behavior occurring (never = 4, occasionally = 3, frequently = 2, always = 1). “Each form is an AutoScore™ Form that transfers the rater’s responses to a Scoring Worksheet via carbon paper. The Scoring Worksheet makes it easier to calculate the SPM-P scores” (Miller Kuhaneck et al. 2010, p. 3). Prior to giving the SPM-P Home or School Forms to respondents to fill out, the Summary Score Sheet must be removed and saved for later use when scoring the items. Based on the SPM-P scoring structure, “a higher raw score always indicates a higher level of problems or dysfunction than does a lower raw score” (Miller Kuhaneck et al. 2010, p. 14).

The SPM-P Home and School Forms generate eight norm-referenced standard subscale scores: social participation (SOC), vision (VIS), hearing (HEA), touch (TOU), body awareness (BOD) (refers to proprioception), balance and motion (BAL) (refers to vestibular function), planning and ideas (PLA) (refers to praxis), and Total Sensory Systems (TOT) (Miller Kuhaneck et al. 2010) (see Table 1). The SOC and PLA subscales have items that represent higher level SI functions that are impacted by sensory input but also include other cognitive and environmental factors. “The VIS, HEA, TOU, BOD, and BAL scales are referred to as the *sensory systems scales* because they address a child’s ability to process direct

sensory inputs. . .the TOT scale is a composite of all of the sensory systems scales, plus additional items that reflect taste and smell inputs” (Miller Kuhaneck et al. 2010, pp. 13–14). The SPM-P items that make up the SOC, VIS, HEA, TOU, BOD, BAL, PLA, and TOT scales (see Table 1) provide information about a number of processing SI vulnerabilities including under-responsiveness, over-responsiveness, sensory-seeking behavior, and perceptual problems (Miller Kuhaneck et al. 2010).

The standard scores (referred to as T-scores) for each subscale derived by both the SPM-P Home and Main Classroom Forms facilitates the classification of a child’s sensory processing functioning into one of three categories for clinical interpretation purposes: (1) the *typical* range (a T-score of 40–59) indicating a child’s behavioral and sensory functioning are similar to that of

Sensory Processing Measure: Preschool (SPM-P), Table 1 SPM-P forms and scales

SPM-P subscales	Number of items
<i>Home Form</i>	
Social participation (SOC)	8
Vision (VIS)	11
Hearing (HEA)	9
Touch (TOU)	14
Body awareness (BOD)	9
Balance and motion (BAL)	11
Planning and ideas (PLA)	9
Total sensory systems (TOT)	58
<i>School Form</i>	
Social participation (SOC)	10
Vision (VIC)	10
Hearing (HEA)	10
Touch (TOU)	10
Body awareness (BOD)	10
Balance and motion (BAL)	10
Planning and ideas (PLA)	10
Total sensory systems (TOT)	55

Source: Miller Kuhaneck, H., Ecker, C., Parham, L. D., Henry, D. A., & Glennon, T. J. (2010). *Sensory Processing Measure – Preschool (SPM-P): Manual*. Los Angeles, CA: Western Psychological Services, p. 4. Reproduced with permission from publisher

Note: The TOT scales include the VIS, HEA, TOU, BOD, and BAL items, plus several items representing taste and smell processing

typically developing peers; (2) the *some problems* range (a T-score of 60–69) indicating that a child exhibits mild-to-moderate difficulties in his/her behavioral or sensory functioning; or (3) the *definite dysfunction* range (a T-score of 70–80) indicating that a child is presenting with significant sensory processing problems that are likely having an impact on his/her daily functioning. “In addition, an Environment Difference (DIF) score allows direct comparison of the child’s sensory functioning between home and preschool/day care environments” (Miller Kuhaneck et al. 2010, p. 3).

Historical Background

The SPM was published in 2007 and the more recent companion SPM-P was published in 2010. When developing the SPM-P, the authors strived to develop items equivalent to the SPM. “The SPM-P authors selected items from the SPM and the *Evaluation of Sensory Processing* (Johnson-Ecker and Parham 2000) item set that could be adapted for use with preschoolers” (Miller Kuhaneck et al. 2010, p. 38). The two sensory processing instruments are designed to provide an assessment continuum for children ages 2–12 years who require longer term follow-up and monitoring.

Psychometric Data

Given that the SPM-P is a relatively new scale being published in 2010, limited psychometric data has been reported about it by external researchers and reviewers. The information reported here focuses on the reliability and validity data reported in the SPM-P manual published in 2010 (Miller Kuhaneck et al. 2010). The SPM-P Home Form and Main Classroom Form were standardized on an American sample of 651 (319 boys and 332 girls) typically developing children ages 2–5 years (Miller Kuhaneck et al. 2010). The sample group corresponded to percentage distribution of categories in relation to gender, age, race, parents’ education level, and

geographical regions from the American 2007 census. The SPM-P authors noted that in comparison to the 2007 census data on ethnicity, a larger percentage of Whites were included in the norming sample compared to Asians, Blacks, and Hispanics (who were underrepresented). In relation to the American Census geographical regions, the children in the sample from the Midwest were overrepresented, whereas the other three regions (North, South, and West) were underrepresented.

The norms for the SPM-P subscales are age-stratified to control for developmental differences between younger and older children with separate norms provided for 2-year-olds and 3–5-year-olds. Two-year-olds were included only if they attended a child care center where a staff member knew them well enough to complete the SPM-P School Form. Five-year-old children were only included in the standardization sample if they had not started kindergarten. None of the children included in the standardization group had special needs or were receiving early intervention services.

To investigate the potential moderating effects of the demographic features of the normative sample, the SPM-P authors used an effect size metric. This metric was used to investigate whether any of the “demographic moderator variables were associated with any clinical meaningful differences between groups in the SPM-P raw scores” (Miller Kuhaneck et al. 2010, p. 38). The effect size data supported the idea of using age-stratified norms and “differences in SPM-P scores due to gender, ethnicity, and SES were small and not likely to have any meaningful impact on the interpretation of test results” (Miller Kuhaneck et al. 2010, p. 40).

Types of reliability data often reported include internal consistency, test-retest/time sampling reliability/temporal stability, inter-rater/inter-scorer reliability, intra-rater/intra-scorer reliability, alternate form reliability, and split-half reliability (American Educational Research Association [AERA], American Psychological Association [APA], & National Council on Measurement in Education [NCME] 1999; Anastasi and Urbina 1997). For the SPM-P Home Form subscale

scores, internal consistency Cronbach alpha coefficients ranged from 0.75 to 0.93 (median = 0.92), while the for the SPM-P School Form subscale scores, internal consistency Cronbach alphas ranged from 0.72 to 0.94 (median = 0.82) (Miller Kuhaneck et al. 2010). “Five of eight Home scales and four of eight School scales have alphas of 0.80 or greater” (Miller Kuhaneck et al. 2010, p. 45). “The Home form resulted in reliability coefficients greater than or equal to 0.73 across all samples. The School form produced similar results across all samples with coefficients greater than or equal to 0.72. Given that there are separate norms provided for the 2- and 3- to 5-year-old samples it is unclear why reliability estimates were not provided for the 3- to 5-year age sample.” (Gokiart and Georgis 2010, p. 3).

Test-retest reliability data were collected on 49 healthy children (23 males and 26 females) ages 2–5 years within a 2-week follow-up period using both the SPM-P Home and School Forms. For the Home Form subscale scores, test-retest reliability coefficients ranged from 0.90 to 0.98 (median = 0.92), while for the Main Classroom Form subscale scores, test-retest reliability coefficients spanned from 0.90 to 0.96 (median = 0.97) (Miller Kuhaneck et al. 2010).

Types of validity often reported for tests include face validity, content validity, criterion-related validity, and construct validity (AERA, APA, & NCME, 1999). Two subtypes of criterion-related validity frequently included are concurrent validity and predictive validity. Two subtypes of criterion-related validity frequently included are concurrent validity and predictive validity, while subtypes of construct validity often reported include factor analysis validity, discriminant validity, convergent validity, divergent validity, diagnostic validity, and rating scale validity (Fawcett 2007; Wolfe and Smith 2007a). Many scales are now using a combination of classical test theory methods (e.g., factor analysis) and item response theory approaches (e.g., Rasch analysis) to examine the construct validity of a measure (Wolfe and Smith 2007b). The SPM-P manual reported a range of validity evidence.

Content validity for the SPM-P forms was ensured since the SPM-P items were derived

directly from the SPM. In turn, the SPM was developed based on items from two previously published scales: those being the evaluation of sensory processing (Johnson-Ecker and Parham 2000; Parham and Ecker 2002) and the School Assessment of Sensory Integration (Miller Kuhaneck et al. 2007). The SPM-P items were also reviewed by a panel of experts and revised based on their feedback. Finally, content validity was demonstrated since the SPM-P items (like those of the SPM) are based largely on the constructs of Ayres SI theory.

A research version of the SPM-P was subjected to confirmatory and exploratory factor analyses (a type of classical test theory approach to validity) to examine its construct validity. Findings of the factor analyses provided support for the basic scale structure of the SPM-P Home and Classroom Forms. Item-scale correlations are reported for the Home and Classroom Forms and provide evidence that supports the separate scoring and interpretation of the SPM-P scales.

The SPM-P authors used Rasch analysis (Bond and Fox 2001) to investigate its rating scale validity structure. With Rasch analysis, two sets of scores are generated, one for participants (person ability scores) and the other for the SPM items (item difficulty scores), expressed by means of a common numerical metric called a logit score (Bond and Fox 2001). The use of a common logit table allows instrument developers to examine the functioning of items with respect to the different ability levels of participants. In other words, the Rasch method provided insights into how the Likert-type scoring categories of the SPM-P item rating scale work together to measure differing amounts of sensory processing difficulties. The rating scale validity results indicated that each of the SPM-P's four rating scale categories (never, occasionally, frequently, always) “is the most probable response for a distinct segment of the underlying variable of sensory processing dysfunction. . .none of the categories are redundant. . .the category sequence of increasing behavioral frequency is properly aligned with the continuum of increasing sensory pathology” (Miller Kuhaneck et al. 2010, p. 55).

Convergent validity was examined by correlating the SPM-P Home Form with the Short Sensory Profile (Dunn 1999) using a sample of 105 children (74 boys and 31 girls) and the Infant/Toddler Sensory Profile (ITSP) (Dunn and Daniels 2002) using a sample of 62 children (42 boys and 20 girls). The SPM-P Home Form total score and the Short Sensory Profile total scores were moderately correlated with each other at $r = 0.62$. Subscale score correlations ranged from 0.06 to 0.59 with the majority of the interscale correlations being significant at $r > 0.20$ (Miller Kuhaneck et al. 2010). The correlations between the SPM-P Home Form and the ITSP were generally strong with correlations ranging from 0.04 to 0.53 with the majority of interscale correlations being $r > 0.25$ (Miller Kuhaneck et al. 2010).

Brown and Subel (2013b) explored the convergent validity the ITSP with the SPM-P Home and School Forms when completed by the parents of a group of 18 children aged between 23 and 36 months of age. Nine of the children were typically developing and nine of the children attended an early childhood intervention service (ECIS) since they were diagnosed with a developmental delay. The SPM-P School Forms were completed by an ECIS staff member for the children with a known developmental disability and a childcare teacher for the typically developing children. Spearman rho correlations were used to examine the associations between the ITSP and the SPM-P Home and School Form subscales. The ITSP and SPM-P Home Form had three of their subscales that were significantly correlated: ITSP Tactile and SPM-P Home Touch processing; ITSP Vestibular Processing and SPM-P Home Body Awareness; and ITSP Vestibular Processing and SPM-P Home Balance and Motion (Brown and Subel 2013b). Similarly, there were three pairs of scales from the ITSP and SPM-P School Form were significantly correlated: ITSP Auditory Processing and SPM-P School Balance; ITSP Vestibular Processing and SPM-P School Balance; and ITSP Oral Processing and SPM-P School Taste and Smell (Brown and Subel 2013b). The authors concluded that the ITSP and the SPM-P Home and

School Forms appear to assess several similar sensory processing factors.

The convergent validity of the SPM-P School Form was examined by correlating it with the Sensory Profile School Companion (Dunn 2006) using a sample of 20 children (16 boys and 4 girls). Correlation results were generally supportive of the convergent validity between the two sensory processing scales. Interscale correlation coefficients ranged from 0.07 to 0.64 with the majority of them being >0.44 (Miller Kuhaneck et al. 2010).

Discriminant validity was demonstrated for the SPM-P based on the data from a separate group (other than the standardization sample) of 242 children receiving occupational therapy intervention. The SPM-P subscales and items were able to differentiate between typically healthy from those with a known clinical diagnosis including autism spectrum disorder (ASD) (Miller Kuhaneck et al. 2010). "Even at the item level, the SPM-P shows robust capacity to differentiate between clinical and nonclinical groups" (Miller Kuhaneck et al. 2010, p. 63).

Brown and Subel (2013a) investigated the known-group validity of the Infant Toddler Sensory Profile and SPM-P Home and School Forms comparing two groups of children between the ages of 23 and 36 months (mean age 32 months, $SD = 2.55$). One group was typically developing and the second group was diagnosed with a developmental delay and was receiving services from an ECIS. The SPM-P School Forms were completed by an ECIS staff member for the children with a known developmental disability and a childcare teacher for the typically developing children. "Four of eight of the SPM-P Home Form subscales had statistically significant differences: touch, body awareness, balance and motion, and planning and ideas. On seven of eight of the SPM-P School Form subscales, statistically significant differences were identified: social participation, vision, hearing, touch, taste and smell, balance and motion, and planning and ideas" (Brown and Subel 2013a, p. 54).

In the SPM-P manual, results about the sensitivity and specificity of the Home and School Forms were reported. At the cutoff score of

$T = 60$, the SPM-P Home TOT scale had a sensitivity of 0.64 and specificity of 0.84 (Miller Kuhaneck et al. 2010). At the same cutoff score, the SPM-P School TOT scale had a sensitivity of 0.52 and specificity of 0.82 (Miller Kuhaneck et al. 2010).

In summary, the SPM-P Home and School Forms is a user-friendly scale that provides a detailed overview of a younger child's sensory processing weaknesses and strengths. Bain and Hunt (2010) commented that among the positive features of the SPM-P are "its quick and easy administration and scoring procedures. Information regarding interrater reliability and correlations across the Home and School forms are mostly lacking in the manual" (p. 3). Gokiart and Georgis (2010) report that the SPM-P "manual provides adequate reliability and validity evidence to support the inferences that are generated from the SPM-P eight scale scores and children's progress can be monitored into school using the companion SPM measure" (p. 3). However, Gokiart and Georgis (2010) also recommend that "additional construct evidence of validity, specifically for the separate age-based normative groups and in comparison to direct measures of function, would further enhance the utility of the tool" (p. 3).

Clinical Uses

The SPM-P provides invaluable information for practitioners related to the identification of and intervention with young children presenting with sensory processing difficulties. It can be used in a range of settings including clinical, community-based, child care, early intervention, early childhood education, hospital, rehabilitation, and research (Henry and McClary 2011). The SPM-P manual notes that it can be "used as either a quick screening instrument or as one component of a comprehensive diagnostic evaluation" (Miller Kuhaneck et al. 2010, p. 13).

The SPM-P forms can be used by a variety of health and education professionals (including occupational therapists, psychologists, early childhood education teachers, social workers, counselors, physiotherapists, speech-language

pathologists, nurses, pediatricians, physicians, and early intervention specialists among others) to evaluate the sensory processing issues of preschool-age children (Miller Kuhaneck et al. 2010). For example, the SPM-P's dual environment approach lets practitioners investigate why a child who functions well in a structured preschool classroom with a predictable daily routine may have problems in certain home environments. "The SPM-P can be administered by itself as a screening instrument, but the examiner should not use the results to make diagnostic or treatment decisions without first assembling the widest possible spectrum of information about the child" (Miller Kuhaneck et al. 2010, p. 4). It is recommended that other sources of information (e.g., medical records, clinical observations, interviews with parents and teachers) be accessed as well.

Olson et al. (2016) completed a multiple case study that investigated the effectiveness and usability of the Sensory Processing Measure-Preschool Quick Tips (SPM-P QT) by parents and teachers to implement an intervention program that was informed by results of the SPM-P. Four children between the ages of two and five who presented with apparent poor sensory modulation and self-regulation at school and at home took part in the study. The selection and application of sensory intervention strategies was guided by the SMP-P QT. When the children were re-assessed using the SPM-P, more improvements were noted on the School version than the Home version. After the study was completed, "feedback by both the parents and the school staff who had selected and implemented the SPM-P Quick Tips indicated progress in social participation and in activities of daily living dependent on sensory processing and praxis (such as tooth brushing, feeding, and sleeping)" (Olson et al. 2016, p. 142).

It has been documented that many children and adults with ASD exhibit sensory processing dysfunction (SPD) (Baker et al. 2008; Baranek et al. 2005, 2006; Dunn 2010; Kientz and Dunn 1997; Leekam et al. 2007; Rogers et al. 2003; Tomchek and Dunn 2007; Watling et al. 2001). The SPM-P manual states that "with moderate to severe

autism, it is not uncommon to see all SPM-P scales elevated in the Definite Dysfunction range” (Miller Kuhaneck et al. 2010, p. 25). It is typically expected that children diagnosed with ASD will have elevated scores on the SOC and PLA subscales. Difficulties in social functioning are one of the hallmark diagnostic criteria for ASD, so it is anticipated that children would have poor scores on the SOC subscale while the “deficits in participation and praxis may be caused or exacerbated by processing deficits in specific sensory systems” (Miller Kuhaneck et al. 2010, p. 25).

In summary, the SPM-P is a welcome addition to the range of tools that practitioners can utilize to assess children diagnosed with or suspected of having ASD. The SPM-P hones in issues indicative of SPD. It is a companion instrument to the SPM and allows monitoring of a child’s sensory processing from 2 to 12 years of age. The SPM-P is based on the same subscale structure and SI theory as the SPM, thus allowing continuity of assessment, intervention, and monitoring from preschool settings to primary school contexts. The SPM-P provides information about two different environments (home and early childhood education settings) based on the input and views of two different respondents (parent/caregiver and preschool teacher). This feature of the SPM-P also fits with the principles of family-centered practice since the opinions, input, and views of parents and care givers are solicited. The ease of scoring and interpreting the results is another attractive characteristic of the SPM-P. These features make it easier for practitioners to explain test results and engage parents in the intervention process.

Both the SPM and SPM-P can be used for evidence-based practice, scientifically based research, differentiated instruction, and monitoring of progress of a child receiving services (Miller Kuhaneck et al. 2010). The SPM-P also has extensive reliability and validity data reported about it in its manual. However, given that it is a relatively new measure, it is recommended that the SPM-P be investigated more closely by external reviewers and investigators so that a related body of psychometric knowledge can be developed about the scale. The SPM-P is highly

recommended for use by practitioners who work with children diagnosed with ASD.

comparison to neurotypical peers (Talay-Ongan and Wood 2000, p. 203). This parent-completed questionnaire includes a total of 54 close-ended items, 9 in each of 6 sensory domains: auditory, visual, tactile, gustatory, vestibular, and olfactory. Items from each modality are randomly distributed within the questionnaire. Respondents rate each item *yes* or *no* based on behaviors typically displayed by the child. Descriptive comments can be recorded for each item at the discretion of the respondent. Example items include:

- My child seems oblivious to (often bad) odors.
- Certain sounds appear to be painful to my child.

Only one paper using the SSQ-R was published in the literature though May 2011.

Sensory Sensitivity Questionnaire: Revised

Renee Watling
Division of Occupational Therapy, Department of
Rehabilitation Medicine, University of
Washington, Seattle, WA, USA

Synonyms

SSQ-R

Description

The SSQ-R was developed as a preliminary tool with the specific aim of informing formal methods of assessing “the nature and extent of sensory hyper- and hypo-sensitivities across all modalities in children with autism” in

Historical Background

The Sensory Sensitivity Questionnaire-Revised (SSQ-R) was developed through a process involving a review of caregiver-report questionnaires of sensory-based performance and behavior by Bettison (1992, 1994), Edelson (1992), and Ayres (1979). Thirty-seven items were selected, revised, and grouped into auditory, visual, tactile, gustatory, olfactory, and vestibular domains. The resulting 37-item measure was pilot tested on a small sample of nine children with autism and age- and gender-matched controls in Australia. Twenty-two items on the initial version were found to discriminate between the children with and without autism in the sample. These 22 items were retained. The remaining items were revised based on qualitative comments provided by the pilot study participants. Additional items were developed through further analysis of the sources originally consulted during test development in order to have an equal number of test items in each sensory domain. The resulting 54-item questionnaire is titled the Sensory Sensitivity Questionnaire-Revised (SSQ-R).

Psychometric Data

Psychometric investigation of the SSQ-R is limited. Authors state that content validity is assumed because items describe behaviors believed to reflect sensory hyper- or hyposensitivities. Concurrent validity is also assumed due to the substantial similarities to other tools examining the same processes. The one published study that examined the SSQ-R reported that 45 of the 54 items were found to discriminate between children with autism and those with neurotypical development using a Cronbach's coefficient alpha criteria of 0.95 (Talay-Ongan and Wood 2000).

Clinical Uses

The close-ended, yes/no response for each item makes this tool likely easy and quick to use. However, it is currently available through the author only; therefore, it is unlikely to be encountered in clinical documentation, though it may be more heavily used in the region where the tool was developed.

Sensory Stimuli

Michelle Lestrud

The Gengras Center, University of Saint Joseph,
West Hartford, CT, USA

Definition

A sensory stimulus is any event or object that is received by the senses and elicits a response from a person. The stimulus can come in many forms such as light, heat, sound, touch, as well as from internal factors. Sensory stimuli can be perceived by the auditory, tactile, visual, gustatory, proprioceptive, and vestibular systems. One characteristic of people with ASD is difficulty with perceiving stimuli as the information is often interpreted differently by the person's brain. Unusual responses to sensory stimuli are typically referred to as hypo- or hyper-sensitive reactions. "Dunn (1997) described the unusual sensory reactions of children by defining hyper-reactivity as having a lowered threshold to sensory input (sensory avoiding), or low tolerance to sensory input (sensory sensitivity), and hypo-reactivity as a higher threshold to sensory input (poor registration) or seeking out sensory input (sensory seeking)" (Jasmin et al. 2009).

SAD

Short Description or Definition

Separation anxiety disorder (SAD) is characterized by excessive fear of separation from a person to whom a child is attached (American Psychiatric Association [APA] 2000). Children with SAD usually worry that if separated from a significant person (usually a parent) something bad will happen to them, such as being kidnapped. Additionally, they may worry that something bad will happen to the attachment figure, such as injury or death. Physical symptoms when separation is anticipated coincide with such worries (e.g., stomachaches). The disturbance stemming from SAD symptoms causes significant interference in the child's home, social, or school life. For a diagnosis of SAD (APA 2000), individuals must experience these symptoms for at least 4 weeks and have an onset before 18 years of age. This area of anxiety is commonly experienced, at a clinical level, by children and youth with ASD.

Categorization

SAD is categorized as a childhood anxiety disorder in the DSM-IV-TR. It is one among a variety of child onset disorders.

Epidemiology

Rates of anxiety disorders in the ASD population have varied between 11% and 84% (Muris et al. 1998; Simonoff et al. 2008). Incidence rates of SAD in the ASD population vary from 0.5% to 19% (Leyfer et al. 2006; Mattila et al. 2010; Simonoff et al. 2008; Sukhodolsky et al. 2008). A review of prevalence rates in typically developing children indicates rates of SAD to be between 0.5% and 20.2% (Cartwright-Hatton et al. 2006). In a comparison study of school-age children with and without a pervasive developmental disorder (PDD), Gadow and colleagues (2005) found similar SAD symptom prevalence rates based on parent report in the PDD clinical sample and the non-PDD clinical sample.

Research indicates that SAD may occur more frequently in children with ASD who have higher cognitive functioning ($IQ > 70$; Sukhodolsky et al. 2008). Of children with ASD and greater cognitive ability, 19% were found to have a co-occurring SAD. SAD commonly presents comorbidly with other anxiety disorders such as generalized anxiety disorder and social phobia.

Natural History, Prognostic Factors, and Outcomes

Little is known about the natural history of SAD in the ASD population. In the typically developing population, many factors such as genetics, anxious temperaments, certain parenting behaviors, and stressful life events are thought to influence the development of anxiety disorders, particularly SAD (Craske 1999; Eaves et al. 1997; Rapee 2001; Wood 2006). One recent treatment demonstrated that improvements in a putative parenting mechanism linked with SAD (intrusiveness) over the course of the acute phase of intervention mediated a reduction of anxiety in school-age children at a 1-year follow-up assessment (Wood et al. 2009). It is hypothesized that when parents take over tasks that children could do for themselves (intrusiveness), it reduces children's self-efficacy for effective action when away from parents, heightening separation anxiety (Wood 2006). Interestingly, intrusive behaviors are associated specifically with SAD symptoms and not other anxiety disorders. The initial clinical evidence from this treatment study highlights the possibility of a dynamic (reversible) effect of intrusive parenting on SAD, but it does not imply that such parenting initially caused the anxiety. Little is known about prognostic factors for SAD in individuals with ASD.

For children with ASD, preliminary studies of CBT for the treatment of anxiety, including SAD, in individuals with ASD have shown positive outcomes with similar rates of anxiety remission as observed among typically developing children with anxiety disorders (Chalfant et al. 2007; Reaven et al. 2009; Sofronoff et al. 2005; Wood et al. 2009a, b). Although various studies have

shown positive responses to CBT, the studies have not specifically examined SAD separately. These studies have treated multiple anxiety disorders, given the finding that most children with ASD referred for treatment have multiple anxiety disorders, not just SAD. Further research is needed to determine what factors are associated with treatment outcomes for SAD symptoms, specifically.

Clinical Expression and Pathophysiology

Children with SAD experience specific cognitive, behavioral, and physiological manifestations of anxiety related to separation (APA 2000). While separation anxiety is normative in infants and toddlers, it typically declines once toddlers reach 30 months of age (Marks 1987; Ehrenreich et al. 2008). Separation anxiety past 30 months of age is atypical and can be SAD-related based on the severity of behaviors and worries. A core anxious belief in children with SAD is an excessive fear that something bad will happen to themselves or a significant person (e.g., parent) if separated, causing significant interference in family, school, and social functioning (e.g., school failure). As a result, children may demonstrate worry when they anticipate a separation (e.g., a child may cry or beg parents not to leave upon learning of an impending separation such as a parent going to run errands while leaving the child at home). Further, there may be places children refuse to go, for example, school, because they are scared to be separated. Children often want the parent near them at bedtime until they have fallen asleep or insist on sleeping with their parents (co-sleeping). It is, of course, important to disentangle whether co-sleeping is a deviation from cultural or family expectations in determining whether this behavior may reflect SAD. Children may be afraid to be alone in their house or in parts of their house even when family members are at home (e.g., child is afraid to be in the bedroom when family is in the living room). They may follow family members around the home or request to be accompanied to different rooms in the home. Children also often have bad dreams

about being separated from loved ones, such as being lost, or being caught in a natural disaster. These persistent fears and worries cause significant distress, and some children experience accompanying physical symptoms such as nausea, vomiting, and headaches.

Sze and Wood (2007) conducted a case study of an 11-year-old girl with concurrent ASD and SAD and described common fears that children with ASD and SAD experience. The youngster was reluctant to be separated from her parents due to worries that she would be kidnapped or that her parents would be killed while they were apart. She would repeatedly call her parents, up to 20 times a day, when they were away from her. Further, during the night, she would frequently join her parents to sleep in their bed. She would not stay over at her grandparents' house or engage in age-appropriate social activities such as sleepovers due to fear of separation from parents.

Evaluation and Differential Diagnosis

Evaluation of SAD in individuals with ASD is still largely conducted with instruments developed for use in the typically developing population. SAD is commonly assessed with semi-structured interviews based on DSM-IV criteria, which involve clinicians, parents, and children. In such semi-structured interviews, clinicians ask the parent and child questions concerning the child's anxiety and distress when separation is anticipated. Further questions focus on worries that the child might have prior to and during a separation, with particular focus on worries about harm befalling the child or parent during a separation. Additional questions focus on avoidance or refusal to go places without parents and avoidance or refusal to go to sleep without their parents. Interviews also include questions on physical symptoms that may occur in conjunction with these worries. After gathering information on specific symptoms, clinicians ask about the impact these anxiety symptoms have in home, social, or academic life. For example, parents may be unable to leave their

child with a babysitter or to be in a separate room from their child while in their house, often resulting in considerable conflict among multiple family members. Additionally, SAD-related symptoms can significantly interfere with children's social life if they avoid play dates or cry in front of friends at separation situations like school drop-off. Further, SAD-related symptoms such as intermittent or chronic school refusal can significantly interfere with a child's academic life. To meet DSM-IV-TR diagnostic criteria for SAD, children must exhibit three of the core symptoms for at least 4 weeks and demonstrate significant interference in child's home, social, or academic life or experience significant distress related to the anxiety symptoms.

In addition to clinical interviews, parent, teacher, and self-reports of these behaviors are useful in evaluating a child for SAD. Although there are often discrepancies among reporters and inter-rater agreement can be modest, such measures are useful in gaining a full understanding of the child's behaviors in different settings. Few measures have been specifically developed to assess SAD in the ASD population, although the Child and Adolescent Symptom Inventory (CASI) developed by Gadow and Sprafkin (1994, 1997) does contain a SAD subscale. Research is beginning to show, however, preliminary evidence for the validity of measures established in the typically developing population in the ASD population (Chalfant et al. 2007; Wood et al. 2009).

The Anxiety Diagnostic Interview Scale for DSM-IV – Child and Parent (ADIS C/P; Silverman and Albano 1996) is a frequently used semi-structured interview conducted separately with the child and parent in order to assess the child's level of anxiety with regard to several different anxiety disorders, including SAD, and has been used in ASD samples (e.g., Chalfant et al. 2007; White et al. 2009; Wood et al. 2009a). The ADIS has very favorable psychometric properties in the typically developing population (e.g., Wood et al. 2002) with preliminary evidence of acceptable inter-rater reliability and

treatment sensitivity in ASD (Chalfant et al. 2007; Wood et al. 2009a, b). From the interview, severity scores are generated for each anxiety diagnosis, ranging from 0 to 8 (with higher scores representing more anxiety and a 0 representing no diagnosis), for each anxiety disorder diagnosis. A score of 4 (moderate) or greater is deemed as clinically significant.

The Multidimensional Anxiety Scale for Children – Child and Parent (MASC C/P; March 1998) is another measure commonly used in the ASD population to assess anxiety. The MASC is a 39-item paper and pencil measure where children and parents rate the child's level of anxiety on a 4-point Likert scale. The MASC is composed of four subscales, including physical symptoms, social anxiety symptoms, harm avoidance, and separation. The MASC has robust psychometric properties in typically developing samples (March et al. 1997); however, its validity in ASD samples is still being determined (Bellini 2004; White et al. 2009).

Evaluation of SAD in the ASD population is complicated by the wide variability in ASD symptomology (Bellini 2004; Wood and Gadow 2010). Similar to other psychiatric conditions, it can be difficult to tease apart SAD symptoms from ASD symptoms. Characteristics associated with ASD such as social difficulties, adherence to routines, and lower adaptive functioning skills may complicate recognition of SAD in these individuals. For example, not partaking in play dates may be symptomatic of SAD if avoidance is due to worries about being separated from a parent and not just symptomatic of ASD-related social deficits. Additionally, adherence to particular bedtime routines may be symptomatic of SAD, and not just ASD, if the bedtime routine requires that the parent staying close to the child throughout the night. Parent assistance in daily living skills due to SAD-related fears (not wanting to separate from parent) also can be distinguished from parent assistance due to lower adaptive functioning skills. For example, a child may need assistance bathing due to lower adaptive skills (ASD-related) or the parent may be providing assistance because the

child insists that the parent be in the same room as him or her (SAD related). Diagnosticians must be skilled in distinguishing between ASD- and SAD-related symptoms to determine the possible impact of SAD on a child's functioning. In addition, there is still considerable controversy over whether "true" psychiatric syndromes occur in the ASD population or if they are an extension of the ASD diathesis (see, e.g., Wood and Gadow 2010). More research is needed to describe the relation between ASD, SAD, and other psychiatric conditions.

Treatment

Various treatments have been suggested for SAD in the ASD population. There is preliminary evidence for the efficacy of modified cognitive behavioral therapy (CBT) in treating SAD in children with high-functioning autism (HFA; Chalfant et al. 2007; Reaven et al. 2009; Sofronoff et al. 2005; Wood et al. 2009). Traditional CBT for typically developing children often consists of psychoeducation and coping skills training. Once new coping skills have been taught, sessions consist of practicing these new skills in increasingly feared situations (Barrett et al. 1996; Kendall et al. 1997).

Enhancements of CBT for individuals with ASD address common impairments associated with ASD in social communication, perspective taking, and understanding of emotions and social cues (Sze and Wood 2007, 2008). There is often an additional emphasis on increasing self-help skills, using cartoons to convey emotions and thoughts, and creating a reward system to increase motivation. Special interests have also successfully been incorporated into treatment to teach coping skills and increase motivation (Sofronoff et al. 2005; Sze and Wood 2007, 2008; Wood et al. 2009).

In the case study by Sze and Wood (2007), a modified CBT treatment plan was effective in treating SAD in an 11-year-old girl also diagnosed with ASD. Characteristic of CBT treatment began

with psychoeducation and coping skills training. To address some of the client's ASD-related symptoms, which can interfere with traditional CBT practices, the therapist used more concrete spoken language and placed a greater emphasis on role playing and visual materials. Additionally, she illustrated abstract concepts using simpler terms and the client's special interests as examples. Further, the therapist employed an interactive rather than didactic style of communication during sessions. A modification of CBT that may be particularly important for the treatment of SAD in the ASD population was the incorporation of work on independent living skills (also see Drahota et al. 2011). The therapist encouraged the parent to gradually reduce the level of assistance in self-help skills and offer choices to increase child's confidence and self-efficacy. After the psychoeducation and skills training components, the therapist developed an anxiety hierarchy with the family to serve as a treatment plan for the rest of the sessions. This hierarchy not only included items pertaining to the child's anxiety and fears but also ASD symptoms. Examples of items included on the participant's hierarchy for SAD were "staying at grandparents' house for 1 h without calling parents, staying at grandparents' house overnight with only one telephone call to parents, and sleeping in my own bed throughout the night without entering parents' bedroom." Additionally, items pertaining to ASD that were included on the hierarchy were "playing and eating with a target peer at recess and lunch, initiating a telephone call to a target peer, and inviting a target peer over for a play date, acting like a good host." The therapist and child discussed coping thoughts for these feared situations. The child was assigned homework to sleep independently, reduce the number of times she called her parents when they were away, and spend time at her grandparents' house gradually without calling her parents. Within 3 weeks of doing these SAD-related exposures, she no longer reported any anxiety concerning separation from her parents. SAD-related worries stayed in remittance throughout the rest of treatment, and she no longer met criteria for SAD at the posttreatment assessment.

Clinical trials that have included SAD as one of the targeted anxiety disorders have demonstrated positive outcomes with modified CBT in this population. Although specific information about the remittance rates for SAD have not been included in the trials, which include children with several types of anxiety disorders, the interventions were effective in relieving anxiety symptoms overall. Wood and colleagues (2009) conducted a randomized controlled trial to examine the efficacy of CBT in 40 children aged 7–11 years old. The treatment program included psychoeducation, coping skills training, and in vivo exposures. Additionally, therapists consulted with schoolteachers and assigned weekly homework for the child to practice at home. At the intake assessments, participants had an average of 4.18 psychiatric disorders, and at posttreatment, over half of the participants in the immediate treatment condition had remission of all anxiety disorders. Chalfant et al. (2007) also conducted a randomized controlled trial for 47 individuals aged 8–13 with HFA and anxiety disorders examining group CBT. At post-assessments, they found that significantly more children in the immediate treatment condition no longer met criteria for an anxiety disorder than the waitlist condition. Reaven et al. (2009) examined group CBT for individuals aged 8–14 with HFA and found significant decreases of anxiety in the immediate treatment versus waitlist group on parent reports of anxiety. Significant decreases in parent-reported SAD symptoms were observed in the immediate treatment group at posttreatment. These studies indicated that modified cognitive behavioral therapy can be an effective treatment modality for treating anxiety disorders in children and youth with HFA.

Medication, relaxation techniques, modeling, behavior modification, and a variety of other therapies have also been explored as treatments for SAD in the typically developing population. While it is likely these practices are used in community settings for children with ASD, there has been little empirical evidence for their efficacy in the ASD population. Selective serotonin reuptake inhibitor (SSRI) medications are frequently prescribed for anxiety in children with ASD, and while there is evidence for their use in the

treatment of anxiety disorders in typically developing children, no clinical trials have examined their efficacy for anxiety reduction in the ASD population. Research on effective treatments for SAD as well as other anxiety disorders in the ASD population is indicated.

Sequential Processing

Yael Kimhi

Education, Levinsky College of Education, Tel-Aviv, Israel

Synonyms

[Analytic processing](#); [Serial processing](#); [Successful integration](#); [Successive processing](#)

Definition

Sequential processing is the mental ability to take in, store, and process information in a serial and temporal manner. It is the ability to arrange separate elements into successive steps, when each step is an indicator for later steps. These elements are linked together in a chain-like way. For example, the ability to recall a series of digits, such as a telephone number, or the flow of words in speech, is dependent upon sequential processing (Angus 1985). Sequential processing refers to the manipulation of stimuli one at a time or feature by feature (i.e., performing a series of movements according to instructions, repeating numbers in a specific order) as opposed to simultaneous processing that emphasizes integrated input formed in holistic units (i.e., face processing tasks, analogies). Sequential processing enables the individual to start and complete a single task, in contrast to parallel, simultaneous processing or multitasking in which multiple information is integrated simultaneously. Inhibition of sequential processing is noticeable in responses to tasks in which participants are requested to locate the presence of a target figure embedded within a complex background (i.e., the Embedded Figures Test: Witkin 1971) in which, for most people, the observation of a familiar global pattern occurs faster than the observation of the component parts and therefore inhibits the perception of the component parts (Gerrard and Rugg 2009).

Individuals with autism are known for their uneven cognitive profiles (Happé 1994).

SEQ

► [Sensory Experiences Questionnaire](#)

A common profile is that of verbal, abstract reasoning, and sequential processing impairments alongside little visual–spatial or organizational deficits (Tonn and Obrzut 2005). A different typical cognitive profile in ASD is that of weak central coherence, in which individuals with ASD attend to specific local details at the expense of global features (Happe and Frith 2006), thereby showing a simultaneous processing deficit.

A disorder in sequential processing may impact various areas of functioning (i.e., tasks that require the concept of first, next, last). Individuals who have a sequential processing deficit may exhibit difficulty with word decoding skills and phonetics, grammar, breaking down arithmetic problems into their component parts, following a sequence of steps or rules, and following oral instructions (Powell et al. 1997).

The sequential processing scale of the Kaufman Assessment Battery for Children (K-ABC; Kaufman and Kaufman 1983) is a measure of problem-solving skills that emphasizes sequence and the processing of information in a serial order. The simultaneous processing scale measures problem-solving skills that involve the using of several processes at the same time.

Synonyms

[Oxazepam](#)

Definition

Oxazepam is a benzodiazepine. The mechanism of action is complicated, but it has been shown that the benzodiazepines bind to specific GABA receptors in the brain and enhance a GABA function. GABA is a primary inhibitory neurotransmitter in the brain. The effect of the benzodiazepines is to promote the influx of chloride ions in specific brain areas. This is the mechanism by which it enhances the inhibitory effects of GABA. Oxazepam is used primarily to treat anxiety disorders, but may also be used as a sleep medication.

Synonyms

5-HT; 5-Hydroxytryptamine

Definition

Serotonin is a central and peripheral neurotransmitter and neuromodulator that also acts as a growth factor in the central nervous system during development. Serotonin is produced from the essential amino acid tryptophan after hydroxylation and decarboxylation and is degraded to 5-hydroxyindoleacetic acid (5-HIAA).

Elevated levels of platelet serotonin have been consistently reported in autism; however, the cause of the elevation has remained elusive. It is also not clear whether brain serotonin production or function is altered in autism. However, alterations in type-2 serotonin receptors in brain and platelets have been reported.

Definition

Serotonin reuptake inhibitors are a class of compounds, most of which are prescription drugs,

Historical Background

The first psychiatric drugs whose mechanisms of action included the reuptake of 5-HT are most of the tricyclic and tetracyclic antidepressants (TCAs). The TCAs are doxepin, first marketed by Pfizer in 1969 as Sinequan; trimipramine, first marketed by Odyssey Pharmaceuticals in 1979 as Surmontil; amoxapine, first marketed by Lederle in 1980 as Asenden; maprotiline, first marketed by Novartis in 1980 as Ludiomil; clomipramine, first marketed by Tyco Healthcare in 1989 as Anafranil; imipramine, first marketed by Novartis in 1959 as Tofranil; amitriptyline, first marketed by AstraZeneca in 1961 as Elavil; nortriptyline, first marketed by Eli Lilly in 1964 as Aventyl Hydrochloride; protriptyline, first marketed by Odyssey Pharmaceuticals in 1967 as Vivactil; and desipramine, first marketed by Sanofi-Aventis U.S. in 1964 as Norpramin.

The development of this group of prescription drugs in the family of classical antidepressants began around the time tricyclic compounds were being developed for the treatment of schizophrenia. Consequently, these drugs were first tested for efficacy in the treatment of schizophrenia, although they were instead found to act as antidepressants in the patients in whom they were studied. The study of the pharmacology of the TCAs led to the development of the selective serotonin reuptake inhibitors (SSRIs), a family of

antidepressants that are generally clinically favorable to the TCAs due to having significantly fewer side effects.

The first SSRI developed was zimelidine; however, its production was discontinued due to its toxicity. The subsequent SSRIs to be developed have fewer side effects than the TCAs while showing similarities in the percent of patients who respond to SSRIs as compared to the TCAs. The six SSRIs that were developed after zimelidine are fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram. Fluoxetine was first marketed by Lilly in 1987 as brand-name drugs Prozac and Sarafem. Sertraline was first marketed by Pfizer in 1991 as Zoloft. Paroxetine was first marketed by GlaxoSmithKline in 1992 as Paxil. Fluvoxamine was first marketed by Solvay in 1994 as Luvox. Citalopram was first marketed by Forest Labs in 1998 as Celexa. Escitalopram was first marketed by Forest Labs in 2002 as Lexapro. Most of these drugs are marketed for the treatment of MDD among other conditions, although fluvoxamine is only marketed for the treatment of OCD in the United States and Europe.

Another family of SRIs developed beginning in the 1990s is the selective serotonin-norepinephrine reuptake inhibitors (SNRIs). The four SNRIs marketed in the United States are venlafaxine, first marketed by Wyeth Pharmaceuticals, Inc., in 1993 as Effexor; duloxetine, first marketed by Eli Lilly in 2004 as Cymbalta; desvenlafaxine, first marketed by Wyeth Pharmaceuticals, Inc., in 2008 as Pristiq; and milnacipran was first marketed by Cypress Bioscience in 2009 as Savella. Duloxetine and milnacipran are not yet available as generic drugs. Milnacipran is marketed in Japan as a treatment for MDD, although it is only FDA-approved for use in the treatment of FM in the United States.

Research on the pathophysiology of depression has led to the development of SRIs outside of these three families such as the serotonin-, norepinephrine-, dopamine-reuptake inhibitors (SNDRI) which inhibit the reuptake of 5-HT, norepinephrine (NE), and dopamine (DA). Although the SNDRI are not currently marketed in the United States, other SRIs that are not of the families of TCAs, SSRIs, or SNRIs such as ziprasidone, trazodone, and dextromethorphan are. One SRI that was used

for obesity management and weight loss, sibutramine with the brand name Meridia, was marketed by Abbott but has been discontinued.

Current Knowledge

Three families of drugs that act as SRIs are the SSRIs, the SNRIs, and the TCAs. Most of these SRIs are generally used to treat MDD, although some of these drugs have other indications such as OCD and other anxiety disorders. Trazodone, with the brand name Olepto, and nefazodone, formerly with the brand name Serzone, are SRIs with 5-HT_{2A} antagonist activity marketed in the United States for the treatment of depression. Other compounds that act as SRIs with 5-HT_{2A} antagonist activity have been developed but have not been marketed in the United States. Cyclobenzaprine, with the brand name Flexeril, is an SRI marketed in the United States as a short-term, adjunctive treatment to physical therapy and rest for muscle spasms associated with acute, painful musculoskeletal conditions. In addition, the opioids pethidine, tramadol, methadone, dextromethorphan, and propoxyphene may have a small amount of SRI activity. The active ingredient in over-the-counter medications dextromethorphan exhibits SRI activity as well as the compounds hyperforin and adhyperforin in St. John's wort and either mesembrine or its metabolite Δ^7 mesembrenone in *Scelletium tortuosum*. A relatively new group of compounds called SNDRI are reuptake inhibitors of 5-HT, NE, and DA; however, these compounds are still in relatively early stages of drug development. Additionally, compounds that act as SRIs and 5-HT_{2C} antagonists have been developed but are not currently marketed in the United States. Other variations of compounds with SRI activity have been reported in the patent literature but require further testing to determine their viability as medications.

The SSRIs are the only SRIs which affect 5-HT receptors without also affecting NE. The six SSRIs that are currently marketed in the United States are fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram. Fluoxetine, with the brand names Prozac and Sarafem, is marketed for the treatment of MDD and OCD. Sertraline, with the brand name Zoloft, is marketed for the

treatment of MDD, OCD, panic disorder, post-traumatic stress disorder (PTSD), premenstrual dysphoric disorder (PMDD), and social anxiety disorder. Paroxetine, with the brand names Paxil, Paxil CR, and Pexeva, is marketed for the treatment of MDD, OCD, panic disorder, social anxiety disorder, GAD, and PTSD. Fluvoxamine, with the brand names Luvox and Luvox CR, is marketed for the treatment of OCD in the United States and is marketed for the treatment of MDD in other countries. Citalopram, with the brand name Celexa, is marketed for the treatment of MDD. Escitalopram, with the brand name Lexapro, is marketed for the treatment of MDD and GAD. SoRI-6238 is another compound known to be an SSRI.

The SNRIs selectively inhibit the reuptake of both 5-HT and NE. These drugs are similar in clinical use to the SSRIs but have the additional effects of treating pain and physical symptoms, such as those of FM. Milnacipran, with the brand name Savella, is marketed just for the treatment of FM in the United States, although it is marketed for the treatment of MDD in Japan. Duloxetine, with the brand name Cymbalta, is marketed for the treatment of MDD, GAD, DPNP, FM, and chronic musculoskeletal pain. Venlafaxine, with the brand names Effexor and Effexor XR, is marketed for the treatment of MDD, GAD, social anxiety disorder, and panic disorder. Desvenlafaxine, with the brand name Pristiq, is marketed for the treatment of MDD. Other SNRI compounds have been developed but have not been marketed in the United States.

The TCAs are a family of SRIs which affect both 5-HT and NE as well as acting as anticholinergic or antimuscarinic agents, alpha-adrenergic antagonists, and antihistamines. Although these drugs seem to have similar efficacy to the SSRIs and SNRIs and may be more effective than those drugs, the TCAs are not as well tolerated and have more side effects than the SSRIs and the SNRIs. Clinically, the TCAs are rarely used due to their side effects. Although these compounds are named for their chemical rings, their side chains are believed to be more important to their functions. The ten TCAs currently marketed in the United States are clomipramine, doxepin, trimipramine, amoxapine, maprotiline, imipramine, amitriptyline, nortriptyline, protriptyline, and desipramine. Different compounds have different

degrees of 5-HT reuptake inhibition; for example, clomipramine exhibits a relatively high amount of SRI activity compared to other TCAs.

Clomipramine, with the brand name Anafranil, is marketed for the treatment of OCD. Doxepin, marketed under the brand name Sinequan, is labeled for use as a treatment for psychoneurotic individuals, alcoholic individuals, individuals with an organic disease with comorbid depression, anxiety, or both; and for individuals with psychotic depressive disorders with anxiety. A formulation of doxepin is also marketed with the brand name Silenor to treat insomnia, and a cream with doxepin hydrochloride as its active ingredient marketed with the brand name Zonalon is marketed for the short-term treatment of pruritus in adults with atopic dermatitis or lichen simplex chronicus. Trimipramine, with the brand name Surmontil; amoxapine, formerly with the brand name Asenden; maprotiline, with the brand name Ludiomil; imipramine, with the brand name Tofranil; a formulation combining amitriptyline hydrochloride with perphenazine, with the brand names Triavil 2–10, Triavil 2–25, Triavil 4–10, Triavil 4–25, and Triavil 4–50; nortriptyline, with the brand name Pamelor; protriptyline, with the brand name Vivactil; and desipramine, with the brand name Norpramin, are marketed for the treatment of depression. Additionally, a formulation combining amitriptyline hydrochloride with chlordiazepoxide, with the brand name Limbitrol, is marketed as a treatment for depression associated with anxiety.

Two important safety issues must be noted with the use of SRIs. The concomitant use of SRIs and monoamine oxidase inhibitors (MAOIs) is a known cause of serotonin syndrome which is potentially lethal. Also, the use of antidepressants in children, adolescents, and young adults may increase depressive symptoms or cause the onset of suicidal ideation; therefore, the appropriate discretion must be used when prescribing SRIs in children or adolescents with depression.

Future Directions

In recent years, the development of new, more efficacious antidepressants has been attempted by combining the effects of SRIs with other

pharmacological effects. The SNRIs are an example of a group of drugs whose development has begun relatively recently which combine SRI effects with NE reuptake inhibition in order to enhance antidepressant effects compared to SSRIs. Since dopamine is thought to be implicated in depression as well, research and development has begun for SNDRIs, compounds with SRI effects, NE reuptake inhibition, and DA reuptake inhibition. At least five SNDRI compounds have been developed. Other compounds being developed and investigated are SRIs and 5-HT_{2A} antagonists; at least 27 of these compounds have been developed to date. The treatment of depression with a combination of SRIs with atypical antipsychotics is another approach being investigated. Other compounds with SRI activity have reportedly been developed, but these compounds require further testing to determine their viability as medications.

[Hyperactivity syndrome](#); [Serotonin behavioral syndrome](#)

Short Description or Definition

Serotonin syndrome is a rare but life-threatening side effect of serotonin (5-HT)-enhancing substances in which overactivation of 5-HT receptors causes various physiological symptoms including diarrhea, agitation, autonomic instability, and cardiovascular collapse.

Categorization

It is a syndrome consisting of mental, autonomic, and neurological disorders.

Epidemiology

Serotonin syndrome is rare, and some reported cases of neuroleptic malignant syndrome (NMS) may actually have been serotonin syndrome since these two syndromes present with similar symptoms and physicians are less familiar with serotonin syndrome than NMS. Although little is known about the prevalence of serotonin syndrome, one retrospective study showed that 4 of the 17 patients using lithium and paroxetine concomitantly developed the syndrome.

This syndrome is more common in individuals taking selective serotonin reuptake inhibitors (SSRIs) than in the general population. Risk factors include dehydration, agitation, and organic cerebral disorders. Onset occurs within 24 h of the administration of the causal agent or agents for all ages and both sexes.

Natural History, Prognostic Factors, and Outcomes

Serotonin syndrome is thought to be caused by the overstimulation of 5-HT_{1A} receptors and potentially involves 5-HT₂ agonists, catecholamines, dopamine (DA), and/or tryptamine as well. Serotonin syndrome is caused by overdose of 5-HT precursors or agonists or the concomitant use of at least two compounds from these groups: serotonin precursors or agonists, serotonin-release stimulators, serotonin reuptake inhibitors (SRIs), and compounds that inhibit 5-HT metabolism in a nonspecific manner including monoamine oxidase inhibitors (MAOIs) and cocaine. Although the current theory regarding the pathophysiology of serotonin syndrome suggests that MAOI-B agents would not precipitate or contribute to serotonin syndrome, evidence suggests that any of the clinically available MAOIs can cause serotonin syndrome. Venlafaxine, trazodone, nefazodone, MAOIs, lithium, tryptophan, meperidine, sumatriptan, buspirone, amphetamines, and

SSRIs have been reported to have caused serotonin syndrome. Serotonin syndrome may also result from the concomitant use of an SRI and methylene blue. Onset of symptoms is abrupt and occurs less than 24 h after the causal agent enters the body. When in mild to moderately severe form, serotonin syndrome usually resolves within 24–72 h although symptoms may last weeks without progression and end when the serotonergic agents are removed. This syndrome may result in death.

Clinical Expression and Pathophysiology

The pathophysiology of serotonin syndrome is not well understood, but excessive activation of serotonin receptors, mainly the 5-HT_{1A} receptors, is thought by many to occur in serotonin syndrome. Other agents which may be involved in the pathophysiology of serotonin syndrome include 5-HT₂ agonists, catecholamines, dopamine (DA), and tryptamine. In serotonin syndrome, the following symptoms are experienced in the order listed: diarrhea; restlessness; agitation, hyperreflexia, autonomic instability; myoclonus, seizures, hyperthermia, shivering, rigidity; delirium, coma, status epilepticus; cardiovascular collapse; and death.

The main symptoms of serotonin syndrome are altered consciousness, autonomic instability, and neuromuscular abnormalities. Observed symptoms include agitation, tremor, myoclonus, hyperreflexia, tremulousness, dysarthria, incoordination, headache, abdominal cramping, bloating, diarrhea, sweating, flushing, delirium, hypomanic symptoms, racing thoughts, pressure of speech, elevated/dysphoric mood, confusion, disorientation, lethargy, diaphoresis, fever, hyperthermia, elevated blood pressure, tachycardia, hypotension, hypertension, and cardiovascular collapse resulting in death.

Evaluation and Differential Diagnosis

Since no single diagnostic test exists for serotonin syndrome, multiple approaches to the differential diagnosis of this syndrome exist. The three components of a differential diagnosis of serotonin syndrome are a history of the use of a serotonergic agent, the presence of signs or symptoms associated

with serotonin syndrome, and the absence of other similar conditions such as NMS. Physicians may consult the Radomski criteria for diagnostic criteria of serotonin syndrome (Radomski et al. 2000).

Both certain diseases and poisonings should be ruled out for a differential diagnosis of serotonin syndrome. The conditions that should be ruled out are catatonia, severe dystonic reaction, encephalitis, hyperthyroidism, malignant hyperthermia, meningitis, NMS, septicemia, stiff man syndrome, herpetic encephalopathy, myocardial necrosis, delirium tremens, and tetanus. The poisonings that should be ruled out are poisonings with adrenergics, anticholinergics, amphetamines, cocaine, 2,4-dichlorophenoxyacetic acid, dinitrophenol, lithium, lysergic acid diethylamide (LSD), MAOIs, pentachlorophenol, phencyclidine (PCP), salicylates, strychnine, and water hemlock. Ruling out NMS is important since it presents in a manner similar to serotonin syndrome. Laboratory tests are indistinguishable between these two syndromes. A drug history including prolonged exposure to neuroleptic agents or discontinuation of dopamine (DA) agonists, lead pipe rigidity, and absence of mydriasis would indicate a diagnosis of NMS as opposed to that of serotonin syndrome.

Treatment

Prevention of serotonin syndrome is attempted by avoiding the concomitant use of SRIs and MAOIs and allowing time between discontinuation of one of these types of drugs and the initiation of treatment with a drug of the other type. At least 2 weeks must be allowed before beginning an MAOI after discontinuing most SSRIs, although at least 5 weeks must be allowed before beginning an MAOI after discontinuing fluoxetine. At least a few days must be allowed before beginning and MAOI after discontinuing a tricyclic antidepressant (TCA).

Treatment consists of the discontinuation of offending agent and the use of intensive care measures as needed while waiting for the syndrome to resolve. Benzodiazepines, cyproheptadine, chlorpromazine, methysergide, propranolol, nitroglycerine, dantrolene, anticonvulsants, mechanical ventilation, paralyzing agents, and cooling blankets

may be utilized to aid in treatment. Supportive care is sufficient in all but severe cases. In severe cases, therapeutic agents can be used, although none of them have shown clear and consistent efficacy for the treatment of serotonin syndrome.

Synonyms

Sertraline hydrochloride; Zoloft

Definition

Sertraline is a prescription drug in the group of selective serotonin reuptake inhibitors (SSRIs) in

the family of antidepressant medications whose active ingredient sertraline hydrochloride has the chemical formula $C_{17}H_{17}NCl_2 \cdot HCl$. This drug was initially FDA-approved for medical use in the year 1991. This drug is FDA-approved for the treatment of major depressive disorder, obsessive-compulsive disorder (OCD), panic disorder with or without agoraphobia, posttraumatic stress disorder (PTSD), premenstrual dysphoric disorder (PMDD), and social anxiety disorder. Risks include onset of suicidal ideation and increased depression in major depressive disorder. Observed side effects include nausea, diarrhea/loose stools, insomnia, somnolence, headache, dry mouth, ejaculation failure, and decreased libido.

Service Delivery Model

Samuel L. Odom

Child Development, University of North Carolina
at Chapel Hill, Chapel Hill, NC, USA

Definition

Service delivery model refers to a set of practices, organized around a conceptual framework, that promote the development, learning, or welfare of individuals with autism spectrum disorders (ASD) and their families (i.e., this entry will not address health services). “Model” implies that a clearly articulated organization of practices exist; “service” indicates that the treatment, intervention, or therapy practices that individuals with autism receive are specified, and “delivery” specifies that there is a method for implementing the service(s) and documenting the quantity and/or quality of the implementation. This definition may be construed broadly or in more discrete terms.

When construed broadly, service delivery model may refer to provisions of service specified by a governmental agency, insurance company, or other human service agency. For example, the Individuals with Disabilities Improvement Education Act (IDEIA) funds services to students with disabilities, including ASD, enrolled in public school programs and infants and toddler with disabilities enrolled in early intervention programs (<http://idea.ed.gov/>). Medicaid agencies within states create waivers that provide funds for service for Individuals with ASD (<http://www.cga.ct.gov/2007/rpt/2007-R-0319.htm>). Similarly, in some states, insurance companies fund services for individuals with ASD, such as speech and language therapy or early intensive behavioral intervention (Young et al. 2009).

Format for Service Delivery

Intervention and treatment services for children and youth with ASD may be delivered in different formats. *Clinic-based services* occur, as the name suggests, in a clinical setting, and often, a trained therapist delivers the service to the child or youth with ASD. For example, a speech pathologist may provide speech. At times, the therapists will also work with parents to show or teach them ways of working with their child at home. An example of a clinic-based service is when a child with ASD receives discrete trial training at a treatment center, as happens for part of the Lovaas Institute model (<http://www.lovaas.com/about.php>), or a child and family attend clinic-based sessions for developmental therapy as occurs with the DIR model (<http://www.icdl.com/dirFloortime/overview/GuidelinesforComprehensiveApproach.shtml>).

Services may also be delivered in the *home or community* setting. In such service delivery models, a therapist or home visitor may travel to the child’s home and work directly with the child, work with the parent to teach her or him to deliver the intervention, or a combination of the two. The content and purpose of these programs vary considerably. For example, Devlin and Harber (2004) had described home-based programs in which the parent delivers discrete trial training intervention for their children with ASD. In contrast, other home-based service models consist of home visitors who support families in promoting communication during natural routines and play (Wetherby and Woods 2006).

A third type of service delivery model is through the *school-based* programs. In this model, children with ASD attend and participate in classes that may be specially designed for students with ASD or that exist in inclusive general education settings. In these service delivery models, the class is led by a teacher and other professionals provide related service at the school. These are the types of services prescribed by the public schools and supported by IDEIA, mentioned previously. A variation on this public school service model occurs in high school, when adolescents with ASD are involved in

community independence and vocational training (Bambera et al. 2007).

A fourth type of service delivery model occurs for adults with ASD during the post-school years. The needs of adults with ASD vary and so do the services. In some communities, agencies provide support and options for residence outside of the family's home, and options may range from group homes to independent community residence with support (Stancliffe et al. 2004). In addition, a goal for many adults with ASD is supported or independent employment, and agencies may provide vocational skills training and supported employment in the community (Mank 2007).

In addition, often there are combinations of the service delivery model just noted. For example, Project DATA (Schwartz et al. 2004) is an early intervention program for children with ASD that operates in a classroom setting, but in which children with ASD also received individual discrete trial training and a home-based component in which staff visit the home to work with the parents on a regular, frequent basis.

Comprehensive Treatment Programs as Service Delivery Models

The more discrete definition of service delivery models refers to intervention or treatment programs that include specifically articulated practices, procedures for assessing implementation, evidence of replication (or use in more than one site), and often evidence of efficacy (Odom et al. 2010). These programs have been also called "comprehensive treatment models" (Odom et al. 2007) or "brand-name" programs (National Research Council 2001).

Historical Background

The initial mode of treatment services for children with ASD were institutional (Kanner 1971), often having a psychodynamic orientation (Ruttenberg 1971). A controversial program established by Bruno Bettelheim (1967) in the 1950s–1960s was based on removing children from the

purportedly damaging influence of their "refrigerator" mothers, with these services again delivered in a residential setting. Partly in reaction to the psychodynamic approach and also changing theoretical perspectives in the field, other models emerged in the 1960s. The two emerging treatment models of the time were the "Lovaas" model (Lovaas 1971) and the TEACCH (Treatment and Education of Autistic and Related Communication Handicapped Children) model (Mesibov et al. 2004). The Lovaas model, which first was known as the UCLA Young Autism Program (Lovaas 1996) and then the Lovaas Institute model, is based on the application of the principles of applied behavior analysis. Its most prominent feature is the use of discrete trial training, although the current Lovaas Institute model includes a wider range of practices. The TEACCH model follows a psychoeducational and social learning theory theoretical framework, incorporates a "structured teaching" approach (Schopler et al. 1971), and proposed, early on, to incorporate parents as the "therapists" for their own children with ASD (Schopler and Reichler 1971).

From the 1980s to early 2000s, comprehensive treatment models continued to develop and followed a broader array of theoretical and conceptual frameworks. For example, the Pivotal Response Treatment model (Koegel and Koegel 2006) and the Walden model (McGee et al. 1999) followed a more "naturalistic" application of applied behavior analysis. The LEAP (Learning Experiences: An Alternative Program for Preschoolers and their Parents) model (Hoyson et al. 1984) incorporated early childhood education orientation, typically developing children, and the application of applied behavior analysis. The DIR model developed by Greenspan and going by the popular name of Floortime followed a clinical, "relationship-based" process (Greenspan and Weider 2006). The Early Start Denver model, also known just as the Denver model, incorporate both developmental and behavioral principles in a clinical (Dawson et al. 2010) and also school-based format (Rogers et al. 2001).

In the early 2000, the National Academy of Sciences convened a committee to review

educational programs for students with ASD, and they identified models that they called “brand-name” programs because individuals often referred to them by the developer’s name or an acronym established for the program (e.g., “the Lovaas model,” “Walden,” TEACCH, LEAP, etc.). The committee concluded that although these service delivery models/comprehensive treatment programs were identifiable and clearly existed, with the exception of the UCLA Young Autism Project, studies addressing the efficacy of these programs were limited.

Current Knowledge

In the ensuing years, comprehensive treatment models continued to be developed and appeared in the literature. In a set of books edited by Handleman and Harris (2006, 2008), developers of comprehensive treatment models described approaches for preschool and school-age children with ASD and their families. To examine the cohesiveness of comprehensive treatment models for young children with ASD, Odom et al. (2010) searched the literature and identified 30 programs. They classified these programs as applied behavior analysis (ABA)-Clinic or Home (e.g., Lovaas Institute, Pivotal Response Treatment), ABA-Classroom Based (e.g., May Institute, Princeton Child Development Institute), ABA-Inclusive (e.g., LEAP, Walden model), Developmental and Relationship-Based (e.g., Early Start Denver model, SCERTS [Social Communication, Emotional Regulation, and Transaction Support]), and Idiosyncratic (e.g., TEACCH, Miller Method). Odom et al. concluded that as a group, programs were strongest in their specification of practices and content inherent in their models and replications by other sites. They were relatively weak on measurement of implementation and evidence of efficacy.

In a review of the literature that examined the evidence of efficacy of comprehensive treatment models, Rogers and Vismara (2008) found that the Lovaas Institute model has the strongest evidence of efficacy, and the Pivotal Response Treatment

has emerging evidence. Conducting one of the most comprehensive reviews of the research literature, the National Standards Project (2009) found evidence for “established” comprehensive treatment models and focused intervention practices. They identified Comprehensive Behavioral Treatment for Young Children and Pivotal Response Treatment as two comprehensive approaches that met their criteria for “established treatments.” Also, they identified developmental relationship-based treatment as an emerging treatment (i.e., some positive evidence, but not enough to meet the criteria for established treatment). A review issued by the What Works Clearinghouse (http://ies.ed.gov/ncee/wwc/reports/ece_cd/lovaas_model/index.asp), however, found that the Lovaas model had potentially positive effects on cognitive development, but no discernible effects on communication/language, social-emotional, or functional behavior.

Future Directions

The field of treatment service delivery has been pushed by the search for the most effective practices for children and youth with ASD and their families. In the past, efficacy research on comprehensive treatment models and services has been limited by funding opportunities. Efficacy studies are expensive, especially if they are school-based and require random assignment of classrooms or buildings rather than individual children and families. Currently more avenues for funding exist for efficacy and effectiveness studies (i.e., through NIH, HRSA, and the Institute for Education Science), and in the future, there will be more scientific evidence documenting the effects of comprehensive treatment models as well as comparison of the relative effects of different models.

With greater confidence in the efficacy of specific treatment and service models will come the desire to “scale up” the implementation of these models. Implementation science (Fixsen et al. 2005) has made great inroads into examining factors affecting the use of model features and quality of service in a variety of fields of human service

areas (Durlak and DuPre 2008). In the future, not only will the specific practices within models be critical for determining the impact of the services provided, other implementation factors such as professional development and training, coaching, and administrative support will separate the effective from the ineffective delivery of services to individuals with ASD and their families.

In the past, the majority of the research and development related to service delivery models has occurred at the early childhood and elementary levels. With the increasing awareness of ASD across the age span has come the recognition of the need for treatment and service delivery models for middle school, high school, and adulthood (Interagency Autism Coordinating Committee 2011). In their strategic plan, the Interagency Autism Coordinating Committee (2011) has identified high school programs for students with ASD as one critical area of need. Effective comprehensive treatment and service models will undoubtedly emerge in the future.

As in every area of life in the twenty-first century, technology will impact the future of treatment and service delivery for individuals with ASD. At the individual level, treatment models and services will design personal technology (e.g., iTouch, Pads, personal organizers) that fosters independence. For example, iPods have been used to prompt individuals through schedules for their school day (Cihak et al. 2010). For students, this may foster a shift from the interpersonal to the “technopersonal” (i.e., increased communication through electronic media). In professional development, there are already websites that display online courses and modules of evidence-based practices, which will be used in training and can be the basis for treatment and service delivery (National Professional Development Center on ASD 2011; <http://www.npdc.fpg.edu>). Following the principles of telemedicine, the easy use of videotelemetry allows supervision and coaching of professionals and parent located at remote sites (Vismara et al. 2009). Currently, technology is advancing faster than the treatment and service delivery science, and it will lead to great changes in the future.

[Service need](#); [Service receipt](#); [Service use](#)

Definition

The provision of services to address health, social, and educational needs and goals. Service utilization has been described as a dynamic interaction between consumers and providers that can be operationalized by describing its continuity (e.g., the degree to which it is provided uninterrupted over time as needed), its comprehensiveness (the degree to which it recognized the full range of needs across time), its accessibility (the facilitation or barriers to receipt), and its productivity (the capacity to generate the sufficient volume of activity required to address needs) (Da Silva et al. 2011). Within the context of autism, service utilization can be driven by need and availability and will inevitably cross various sectors (social services, education, health) as a result of the multifaceted nature of the condition. Service utilization also varies in response to

demographic, clinical, and systemic factors over time. Some needs are acute, while others chronic.

There is considerable research on services utilized by children with autism (e.g., diagnostic, behavioral intervention, special education, speech and language therapy, financial supports, and supports for family), with home and education supports varying by school district or parent socioeconomic status. Given the high rate of physical and mental health comorbidities, several studies have documented the high volume of health service utilization specifically. Compared to children without autism, those with autism have higher rates of pediatrician, specialty care (including speech therapy, occupational or social skills therapy, physical therapy, psychotherapy, and neurology), hospitalization, and emergency department (ED) visits within a 1-year period (Cummings et al. 2016). Adults with autism are also more like to visit the family physician, pediatrician, psychiatrist, neurologist, and gastroenterologist and to visit the ED for psychiatric reasons and be hospitalized overall and for psychiatric reasons, compared to peers without developmental disabilities (Weiss et al. 2018). There is some question as to whether high rates of service use are specific to autism though, with recent large-scale studies highlighting higher rates of health use in adolescents and young adults with many different kinds of developmental disabilities (i.e., those with autism, with fragile X syndrome, or with other intellectual disabilities) relative to non-affected peers (McDermott et al. 2015). At the same time, large-scale administrative studies continue to highlight a higher volume of psychiatric-related health service use in adults with autism compared to those with other kinds of developmental disabilities (Weiss et al. 2018).

While service productivity may be high, accessibility, continuity, and comprehensiveness may be low, with many individuals reporting difficulties in receiving services that correspond to priority needs (Lai and Weiss 2017). Unmet needs have been described with regard to healthcare, therapeutic, and family support services. Individuals with autism often experience many barriers to service receipt across the lifespan and sectors, as

a result of wait lists, a lack of resources, and inadequate service provider skills ((Hodgetts et al. 2015). Unmet needs have been associated with clinical severity and demographic factors (e.g., age, race, socioeconomic status, or rurality). Systemic variables are also important to consider, as in some jurisdictions, only individuals with a certain severity of autism or with co-occurring intellectual disability are eligible for services. Service availability is also related to how services are funded and the capacity of providers. There are significant transition-based issues with service utilization, with gaps in provision being associated with moving from child to adult contexts. It is important to note that barriers to service receipt at one point in time can influence services needed and used in the future. For example, good continuity of care can result in a reduced use of emergency-related services in individuals with autism and other developmental disabilities (Wood et al. 2007). Continued research is needed to understand trajectories of service utilization over time.

Set Shifting

- Cognitive Flexibility

Setting Events

Jeffrey Danforth

Department of Psychology, Eastern Connecticut State University, Willimantic, CT, USA

Definition

Setting events are prior events or conditions, internal or external to the individual, that influence the probability and form of behavior presented by the individual. Setting events are related to the concepts of discriminative stimulus and establishing operation. A discriminative stimulus is an antecedent stimulus in the presence of which a response is likely to occur

because in the past, the response has been more successful in the presence of that stimulus than in the absence of that stimulus. An establishing operation (sometimes referred to as motivating operation) is an environmental event that affects the individual by momentarily altering the reinforcing effectiveness of a consequence and altering the rate or intensity of behavior that has resulted in that consequence (Michael 1993). Typical stimulus control analyses focus on brief temporal associations between stimuli and response, focusing on stimuli contiguous with the behavior of interest. The distinction between setting events and the concepts of discriminative stimulus and establishing operation is that setting events do not refer to the simple presence or absence of discrete immediate objects or events. Setting events are more complex events that may overlap the behavior of interest or precede the behavior of interest by immediate or large temporal gaps, and setting events may include the individual's response to events. The key distinction is that the setting events might be temporally distant from the behavior of interest and that they could include stimuli within the individual. Thus setting events could occur in a wholly separate time and place, long before the behavior of interest, or they could occur while the behavior of interest is happening. The section "[Current Knowledge](#)" presents examples of setting events that may influence the behavior of individuals with autism. The events could have occurred hours or days before, or they include the behavior of the individual, yet the setting events still have an impact on the behavior of the individual (Wahler and Fox 1981).

Historical Background

Early research in applied behavior analysis focused on the immediate antecedents and consequences of behavior. Setting events emerged from efforts to understand the potential influence of environment interactions that were not immediate (Kantor 1959).

Current Knowledge

There are many setting events known to influence the behavior of individuals with autism. It is critical for those working and living with individuals diagnosed with autism to identify known setting events, the behavioral circumstances people recently or historically passed through. Knowledge of the individual is equally important as knowledge of autism because a specific setting event will likely be functional for some people and not for others. Parents and teachers who have a lot of experience with a specific person are the best sources for determining which setting events are influential. Knowing how a specific setting event might influence a specific behavior in the individual has the advantage of allowing time to prepare positive behavior supports (Lucyshyn et al. 2002).

Examples of antecedent interventions are presented below. The emphasis on understanding how setting events influence the actions of individual people cannot be overstated. The adage, "once you have seen one person with autism, you have seen one person with autism," is quite applicable. The details of the influences of setting events are highly individualized across people with autism.

Types of Setting Events

Environmental. Characteristics of setting events in the environment may include if the setting is loud and chaotic versus quiet and orderly, a crowd of people versus a few people, daily routines versus high-rate novelty and unpredicted schedule changes, difficult demands versus previously mastered demands, demands that require a long time to complete or concurrent demands presented at a high rate versus demands that can be completed quickly (Carr et al. 1996).

Physiological. Physiological setting events of greatest interest within the individual are those that make the person with autism less amenable to reinforcement, less tolerant of frustration, and more likely to engage in intense behavior

reinforced by attention or escape from stress. Such events may include pain (e.g., earaches, toothaches, sunburns, and constipation), illness (e.g., seasonal allergies), discomfort (disorienting medication), lack of sleep or fatigue, recent seizure activity (Carr and Smith 1995), and menstruation (Carr et al. 2003). In some cases, setting events are related to sensory dysfunction that includes auditory, tactile, or visual defensiveness. Therefore, individual behavior may be influenced by loud, high-pitched, or sudden noise (e.g., vacuum cleaners or electronic pencil sharpeners), clothes that are too tight or too loose, seat belts that are too tight, sensations that are too gentle such as a soft touch, or light that is too bright, fluorescent, or blinking.

Social. Social setting events may have occurred earlier in the day, on the bus to school, just before or during the time of interest. These events could include interpersonal conflict, novel people, or the absences of selected people typically present (the substitute teacher syndrome).

Immediate antecedents. Discrete, immediate events that may influence the subsequent behavior of individuals with autism include failure to pass contracts or earn rewards that include preferred activities or tangible reinforcers, the delay or loss of scheduled rewards or preferred activities due to unforeseen events (e.g., cannot go on the scheduled trip to the park because of inclement weather, cannot visit a friend because they are ill), or simple instructions, demands, or requests to engage in required activity versus opportunities to choose (Carr and Newsom 1985).

Psychological states. Finally, internal behavioral characteristics of the individual can serve as setting events that alter the reinforcing properties of consequences. Psychological states may include sad mood, stress, perseverative thinking or overfocused thoughts, specific fears, or the absence of specific stimuli. For example, a comfort item such as a blanket or a specific toy might set the occasion for desirable behavior. Conversely, the absence of the comfort item might set the occasion for intense anxious fear responses.

Functional Assessment

Knowledge of potential setting events highlights the importance of functional assessment. However, functional assessment needs to evaluate more than the current setting and the events immediately preceding the behavior. The functional assessment may need to assess events long preceding the immediate behavior of interest and behavior within the individual. In some cases, an indirect functional assessment that utilizes subjective data provided by caregivers may be more practical than an experimental functional analysis. If behavior is disrupted by global occurrences such as weather patterns (e.g., snow days that disrupt school routines), it might be systematically difficult to alter those events. However, an event that is not manipulable in an experimental sense may still affect the behavior.

Setting events are not unique to individuals with autism. What is unique is the wide range of idiosyncratic events that may serve to influence the behaviors of a person with autism and the wide range of maladaptive responses that might be evoked. The setting events described above can lead to behavior ranging from resistance to teaching to tantrums, aggression, self-injurious behavior or stereotypical repetitive behavior. It is important to avoid the temptation to seek rationale explanation for the impact of a setting event. If pencil sharpeners disturb a child, we may never know why, but that does not reduce the impact of the pencil sharpener.

Intervention

As suggested above, a functional analysis of setting events can lead directly to intervention strategies. Staff and parents may (1) prevent a stressful event from occurring or remove the person from that event before the person is exposed to the stressor, (2) ensure that specific stimuli that occasion success are present, (3) make alternate preparations to increase the likelihood of success (e.g., foreshadow an event with a student and then rehearse potential adaptive responses), or (4) program incremental exposure to setting events to increase opportunities to adapt and respond successfully.

There are advantages to interventions that focus on antecedent programming. Sometimes

reinforcement procedures do not work because they are difficult to consistently apply or because of difficulties identifying effective reinforcers. There are numerous concerns about the role of punishing consequences. In contrast, caretakers may be more willing to apply antecedent intervention. “Antecedent intervention has the purpose of preventing the occurrence of challenging behavior . . . an antecedent approach manipulates conditions to eliminate the probability of undesirable behavior” (Luiselli 2008, p. 394). With the help of parent and teacher input, indirect or descriptive functional assessments can lead to hypothesis statements about the strength of setting events or events that correlate with behavior. The outcomes may be hypotheses that are useful in a practical sense on a daily basis.

The Setting and the Schedule

For example, teachers could assess the presence of psychological or medical states. Upon arriving at school, personnel may ask questions such as “Is he overfocused on anything today? Did he talk about seeing insects on the bus ride to school?” or “How did he sleep last night? Is his nose still stuffy?” Knowledge of a person’s physiological or medical state or social interactions earlier that day may result in temporary curriculum changes (e.g., more choices, Cannella et al. 2005; preferred tasks, shorter tasks, slower pacing, Luiselli 2008).

Knowledge of sensory dysfunction can lead to simple solutions. For example, the noise occasioned when a classroom chair slides across the floor might evoke high-rate hand flapping and an emotional tantrum. An inexpensive solution observed in many classrooms is tennis balls attached to legs of chairs, so noise is suppressed. The importance of environmental structure leads to careful consideration of predictable scheduling.

Skill building. Functional communication (O’Reilly et al. 2006) can help teach adaptive skills when stressful settings are identified. A teacher could help a student prepare for a challenging lesson by teaching the student an adaptive response such as “I need help.” In turn, the teacher could provide assistance and praise contingent on the student’s request for help. If noisy settings elicit emotional reaction, in separate discrete trials, staff could gradually expose the student to

incremental increases in the noise, allowing for sensory adaptation (habituation). These hypothetical strategies can emerge directly from understanding how an environmental event influences the behavior of the individual child.

Future Directions

Setting events are important, but compared with discriminative stimuli, setting events are less likely to be a focus of experimental research or a functional analysis. One reason is that setting events can occur in remote time long before the behavior of interest, and functional analysis tends to focus on the current setting or stimuli that immediately precede the behavior of interest. Another reason setting events are less considered is that functional analysis most often focuses on reinforcing consequences, whereas some setting events affect behavior regardless of the consequences. Finally, since our original understanding of the law of effect, the majority of behavior modification research has focused on manipulating consequences of behavior. Nonetheless, the advantages and successes of antecedent interventions bode well for proportionately more research.

Sex Chromosomes

Ellen J. Hoffman

Albert J. Solnit Integrated Training Program, Yale Child Study Center, Program on Neurogenetics, Yale School of Medicine, New Haven, CT, USA

Synonyms

X and Y chromosomes

Definition

The sex chromosomes (X and Y) determine male (XY) and female (XX) genetic sex. The X chromosome is large and contains considerably more genetic material than the Y chromosome (155 megabases (Mb) of DNA vs. 60 Mb) (Jorde et al. 2010). Sex-linked disorders are caused by mutations on either the X or Y chromosome and demonstrate characteristic modes of inheritance that distinguish them from disorders caused by mutations on the autosomes, or the nonsex chromosomes. For example, X-linked mutations cannot be transmitted from father to son, unlike autosomal mutations, and are more likely to affect males, because males have only one X chromosome (Jorde et al. 2010).

Because autism is four times more likely to occur in males than females and is highly heritable, studies have examined the extent to which genes found on the X chromosome might contribute to the etiology of autism (Skuse 2000, 2007). That is, early studies questioned whether autism is an X-linked disorder, based on the male predominance. However, there is no evidence from genome-wide linkage scans to suggest a simple pattern of sex-linked inheritance (Skuse 2000, 2007). This is consistent with findings from recent large-scale genome-wide studies that are revealing considerable heterogeneity in the genetic architecture of autism such that multiple genes on different chromosomes likely interact to confer risk (State 2010).

Although idiopathic autism is highly heterogeneous and characterized by a complex pattern of inheritance, studies of rare monogenic syndromes that are associated with autism have been instrumental in identifying genes that are likely to confer risk (State 2010). While these susceptibility genes are found throughout the genome, a number of them are located on the X chromosome. These include *fragile X mental retardation protein*, the gene that causes fragile X syndrome, which is highly associated with autism (Moss and Howlin 2009). In addition, Rett syndrome, which occurs almost exclusively in females, is caused by mutations in the X-linked *MECP2* gene (Moss and Howlin). Another important X-linked

susceptibility gene is *neurexin 4X* (*NLGN4X*), which was identified in studies of two families with autism, one of which included individuals with autism and intellectual disability, carrying truncating mutations disrupting this gene (State 2010).

Given the considerable genetic heterogeneity and lack of evidence for a simple pattern of X-linked inheritance, the cause of the higher frequency of autism in males is not known. One hypothesis is that imprinting of genes on the X chromosome may lead to the expression of protective genes on the paternally inherited X chromosome in females (Skuse 2000). Another question is whether X-linked syndromes of intellectual disability, which are more common in males, account in part for the male predominance, yet severe intellectual disability occurs more often in females with autism (Skuse 2007). One recent model addresses the overlap of autism and intellectual disability in the context of emerging observations regarding pleiotropy, suggesting that susceptibility genes may confer risk for both autism and intellectual disability, and that the expression of one or the other is influenced by the combined effects of genetic, epigenetic, and environmental factors during development (State 2010).

Sex Differences in ASD on Restricted and Repetitive Behaviors and Interests

Tyler McFayden

Department of Psychology, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Definition(s)

Restricted and repetitive behaviors and interests (RRBI) is a symptom cluster of autism spectrum disorder (ASD), which include stereotyped or repetitive behaviors, sameness behaviors, restricted interests, self-injurious behaviors, and sensory processing differences (American Psychiatric Association 2013). The *Diagnostic and Statistical Manual of Mental Disorders Fifth Edition* defines these items as follows:

- Stereotyped and repetitive behaviors are behaviors that happen over and over again in an exact way (e.g., playing with the same toy in the same way, abnormal or excessive repetition of the same speech) or unusual motor movements such as hand-flapping or body rocking.
- Sameness behaviors are the insistence to perform actions in the same way including insistence on routines, anxiety surrounding changes in plans, and resulting difficulties with changes in schedules.
- Restricted interests are interests, hobbies, or preoccupations that are unusual in their intensity and in breadth that often occupy most of an individual's time and focus.
- Self-injurious behaviors are behaviors that result in bodily harm and are inflicted by oneself, including skin picking; hair pulling;

biting, hitting, or pinching oneself; head banging, etc.

- Sensory processing differences include a wide array of sensory features, such as hypo- or hyper-reactivity to sensory input (e.g., sounds, pain), sensory seeking behaviors (using senses to explore the world such as smelling objects or people), and sensory avoiding behaviors (e.g., textures, sounds, smells, tastes that may be aversive).

RRBI are commonly measured by three instruments:

1. ADOS-2 (Autism Diagnostic Observation Schedule-Second Edition; Lord et al. 2012) RRB subscale
2. ADI-R (Autism Diagnostic Interview-Revised; Lord et al. 1994) RRB subscale
3. RBS-R (Repetitive Behavior Scale-Revised; Bodfish et al. 2000).

Historical Background

RRBI is one of the two core symptom clusters used to diagnose ASD and has been a core symptom cluster of autism since its very conception as a pervasive developmental disorder (PDD) in 1980 in the *DSM-III*, although RRBI was then referred to as “bizarre responses to the environment” (APA 1980). However, RRBI has garnered attention for its presenting sex differences in ASD. In particular, RRBI is suggested to be less predictive of an ASD diagnosis for females relative to males. Thus, sex differences in the RRBI domain have been studied to better understand the sex discrepancy (i.e., larger male to female ratio) in current ASD diagnostic rates (Baio et al. 2018).

Current Knowledge

RRBI, when studied as a unitary construct, often reveals no significant sex differences in ASD. These results have held true in toddlers diagnosed at 24 months of age (Lawson et al.

2018), in older toddlers (4 years; Carter et al. 2007), in older children (Banach et al. 2009), and in older adolescents and adults after controlling for ASD severity (Harrop et al. 2015; Holtmann et al. 2007). However, looking into RRBI subscales indicates subtle sex differences with ASD that may not be detectable when looking at the RRBI domain as a whole.

Using the parent-reported RBS-R, previous work has noted that varying sub-domains of RRBI are not as predictive of an ASD diagnosis for females as for males (Antezana et al. 2018; Duvekot et al. 2016). Sex differences in RRBI items on the RBS-R emerged for eight different items, including “pulls hair/skin,” “fascination with movement of object,” “hand/finger mannerisms,” “hoarding/saving,” “rubs or scratches self,” “object usage,” “insists on sitting at the same place,” and “preoccupation with parts of an object.” Overall, females demonstrated fewer stereotyped and restricted behaviors, including restricted interests, but more compulsive, restricted, self-injurious, and sameness behaviors than males (Antezana et al. 2018). These results are particularly interesting as they indicate some RRBI areas where females have greater or fewer RRBI scores, which may explain why no sex differences emerge when reviewing RRBI as a unitary construct: these subtle differences are washed out. Specific subscales of RRBI are discussed below.

Stereotyped and Repetitive Behaviors

The RRBI domain includes many different types of behaviors and manifestations (see Definitions); however, across all behaviors, females demonstrate decreased stereotyped and repetitive behaviors. These differences in stereotyped and repetitive behaviors are present across development and include decreased rates of preoccupations, routines, lining up of objects, and stereotyped mannerisms (Antezana et al. 2018; Hattier et al. 2011; Hiller et al. 2014; Nicholas et al. 2008). Thus, across development and the range of stereotyped and repetitive behaviors, females appear to demonstrate fewer behaviors than males on the spectrum.

Sameness Behaviors

Little work has investigated sex differences in sameness behaviors. As mentioned above, RBS-R items indicate stronger female insistence on sameness than males, as indicated by responses to items such as “insists to sit in the same place” (Antezana et al. 2018). Other results have indicated that insistence on sameness (IS) is a distinct subscale from the other behaviors included in RRBI and may present with unique manifestations relative to other behaviors. As IS has been related to communication and cognitive performance in ASD (Szatmari et al. 2006), it is expected that sex differences in IS are present; however, this area is underexplored.

Restricted Interests

Females present with fewer parent- and teacher-reported restricted interests than males (Beggiato et al. 2016; Hiller et al. 2014) that are also lower in severity (McFayden et al. 2018). Not only are these interests different in severity and frequency, but females present their interests in a different fashion relative to males, which may make them harder to detect in females. Females demonstrate greater interests in living organisms, humans, and dolls, which appear social in nature, and may even discuss their interests differently by conveying them in more socially appropriate ways (e.g., writing letters to animal activists and engaging with others) and using less rote presentations of facts or figures relative to males (Mandy et al. 2012; McFayden et al. 2018). Taken together, females have fewer restricted interests, which are lower in severity, and also conveyed and discussed differently than those of males; all of which may make restricted interests more difficult to identify and diagnose in females with ASD.

Self-Injurious Behaviors

Sex differences in self-injurious behaviors are not detectable in toddlers or preschoolers (e.g., Schroeder et al. 2014 and Solomon et al. 2012), but sex differences begin to emerge in school-aged children and continue through adulthood (Beggiato et al. 2016). Females present with greater self-injurious behaviors in the forms of hair pulling, scratching, and cutting (Antezana

et al. 2018). When including non-suicidal self-injurious behaviors (NSSIs), the same pattern of sex differences remains: females endorse greater NSSIs than males starting in adolescence and continuing into adulthood (Maddox et al. 2016). These sex differences in ASD also reflect sex differences in typically developing populations, where females engage in self-injurious behaviors and NSSIs at a greater frequency than males (Bresin and Shoenleber 2015).

Sensory Processing Differences

Overall, little work has been done looking at sensory feature sex differences in autism. Generally, sensory features are similar between males and females. In one work, parents of males indicated greater difficulty with physical sensory features (“endurance/tone” on the Short Sensory Profile; Bitsika et al. 2018). However, this one sensory difference may, in fact, relate more to stereotyped motor movement sex differences in ASD, as discussed above. Sex differences in sensory features remain an underexplored area.

Neurophysiology

Sex differences in RRBI in autism have also been explored neurophysiologically by looking at brain structure, brain function, hormones, and neurotransmitters across males and females with autism spectrum disorder. Results indicate significant sex differences related to RRBI that are visible at the neural level. Structural MRI indicates sex differences in cortical thickness, intraparietal sulcus, gray matter, motor cortices, and the cerebellum, which are linked to RRBI (Supekar and Menon 2015; Van’t Westeinde et al. 2018). Hormonally, sex differences in arginine vasopressin and oxytocin were related to sex differences in RRBI (Miller et al. 2013). Together, there is clear evidence to suggest behavioral and neurophysiological sex differences in RRBI in ASD.

Summary

Subtle sex differences in RRBI in ASD are present. Females have fewer stereotyped/repetitive behaviors and restricted interests but have more self-injurious behaviors and insistence on sameness than males. At this point, not enough has

been conducted in the field of sensory features to be able to draw strong conclusions. When viewed as a whole, the sex differences in RRBI in autism mirror the sex differences in typically developing populations quite well: females present with more “internalizing” features, whereas males present with more “externalizing,” easily observable features. This generalization holds apart from self-injurious behaviors, which are observable behaviors and also more common in females than males.

Implications

Importantly, these differences have implications for diagnostic measures. The female presentation of stereotyped/repetitive behaviors and restricted interests is less severe and less noticeable than males and in fact may not be present to a detectable extent by select diagnostic measures. This work highlights important future directions for research and clinical assessment, discussed below.

Future Directions

Future research must investigate RRBI by looking into the sub-components instead of only reviewing RRBI as a unitary construct. There are several underexplored areas of RRBI sex differences including sensory processing features (e.g., hypo-/hyper-reactivity to sensory input), stereotyped speech (e.g., echolalia), and insistence on sameness. Measurement of RRBI should be better specified to indicate whether RRBI is measured by frequency of behaviors (e.g., how many times are they occurring?), severity or intensity of behaviors (e.g., how extreme or intense is this behavior?), or the behavior’s interference in family or social life (e.g., how much is this behavior getting in the way?). As comorbidities of ASD are becoming better understood, future directions also include studying how comorbid psychopathology impacts RRBI presentation of sex differences, especially disorders that already present as more common in one sex over the other (e.g., ADHD in males; anxiety in females). Lastly, future research on the social construct of gender self-identification and its impact on RRBI and other

ASD criteria will aid in furthering the field’s understanding of sex and gender differences in ASD, as well as understanding diagnostic specificity.

Sex Education

Lisa Wiesner

Pediatric and Adolescent Medicine, Orange, CT, USA

Definition

Sexual awareness comes early for most children. By age 3 years, most children recognize that girls and boys are different. An understanding of where babies come from and later on of the changes in one's body at puberty develops through interactions with many people: siblings, parents, other family members, peers, and teachers. These interactions may be difficult for people with ASDs.

People used to think that the social problems associated with autism prevented sexual interest or relationships. We now know that is not true. Early intervention as well as an emphasis on programs in the community has helped more people with ASDs to have very meaningful relationships, including sexual relationships. Parents of adolescents with ASDs, like many parents, may find it difficult to view adolescents as sexual beings, and they may worry about the adolescent being taken advantage of.

Children learn early that there are different rules for private and public behavior and for who can touch what, where, and when. Adolescents need to cope with distinctions between love and sex and learn about the importance of contraception and prevention of sexually transmitted infections as well as issues of separating from their families and developing long-term relationships. These issues may be more difficult for children on the autism spectrum because of language and communication difficulties, social issues, and varying cognitive levels. Learning about sexuality may not occur at the same age or in the same ways for children with ASDs. Peer relationships may be lacking, and other avenues for socializing may be lacking. It may be harder for children with ASDs to learn the difference between what is okay to think and what is acceptable to say or do. The distinction between private and public behavior

may be poorly understood, and the tendency to be very literal may cause misunderstandings.

It is important to make the learning process about sexuality as positive as possible and to help the child learn what not to do as well as what to do. The ultimate goal is to help the adolescent form a more positive view of himself or herself.

In general, parents of adolescents and young adults with ASDs should help dealing with emerging sexuality by having open discussions, with information at a level that is appropriate for the individual. Socially acceptable behaviors should be made clear. Sex is only one part of what needs to be discussed. The role that relationships play in sexuality and the differences between friendship and a sexual relationship need to be taught.

Adolescents with Asperger's disorder or autism can at times be quite preoccupied with sex or with wanting a girlfriend or boyfriend. These can be age-appropriate concerns but sometimes cause awkward situations when approaches are made in an unconventional manner.

Privacy and modesty are important concepts that may be difficult for children and adolescents with ASDs to understand. Difficulties in generalization can make these hard to teach and understand. Bathroom use early on can be a place to begin this teaching.

Masturbation can be an issue with any child. This can be a source of discomfort for parents and teachers. The distinction between private and public behavior may be hard to learn at times. This at times can be a problem in school. Allowing the student opportunities for frequent movement or objects to manipulate with the hands as an alternative activity may be helpful. Exercise can also be helpful. The occupational therapist or specialized teacher may be helpful in coming up with strategies for teaching the adolescent or young adult with an ASD that masturbation is not appropriate at school.

Teaching about boundaries is another important issue. Parents are frequently worried about the possibility of sexual or physical abuse. Abuse or inappropriate sexual behavior can be issues. Most children with ASDs are closely supervised and that will hopefully prevent either of these

problems. For verbal children, teaching the “no, go, tell” strategy may be useful. This method is described by Schwier and Hinsburger (2000).

Occasionally individuals on the autism spectrum experience difficulties in relation to gender identity. Also occasionally inappropriate sexual comments or requests can lead to legal entanglements.

Sex Hormones

Ellen J. Hoffman

Albert J. Solnit Integrated Training Program, Yale Child Study Center, Program on Neurogenetics, Yale School of Medicine, New Haven, CT, USA

Synonyms

Androgens (male sex hormones); Estrogens (female sex hormones)

Definition

Sex hormones, including testosterone and estrogen, are produced by the gonads, or sex organs. In addition to their role in the development of the reproductive system, these hormones serve important functions in brain development, such as controlling the growth and survival of nerve cells, or neurons (Keller et al. 2008). Both testosterone and estrogen exert their effects on neurons by binding to protein receptors within the cell, which, in turn, directly control the expression of specific genes in these cells (Keller et al. 2008).

The higher frequency of autism in males (4:1) has raised questions about the effect of sex hormones on the risk of developing autism (Keller et al. 2008). One possible explanation for the male predominance, given the genetic risk of autism, is that sex hormones have a modifying effect on an underlying genetic predisposition (Keller et al.). According to this theory, sex hormones may influence the penetrance of a risk gene such that males

carrying a particular mutation may be more likely to develop symptoms of autism than females with the same mutation due to their exposure to different sex hormones during brain development (Keller et al.). It has been proposed that sex hormones may exert this modifying effect via an epigenetic mechanism, that is, by modulating the levels and timing of gene expression by altering chromatin structure (Kaminsky et al. 2006).

One group of researchers led by Simon Baron-Cohen has proposed an “extreme male brain” theory of autism, which posits that traits associated with autism represent a more marked version of a male pattern of cognitive processing (Auyeung and Baron-Cohen 2008; Baron-Cohen et al. 2005). According to this theory, females have a greater tendency toward “empathizing,” or understanding another person’s emotions, while the tendency of males is toward “systematizing,” or analyzing a system based on rules. Baron-Cohen suggests that individuals with autism function in a more extreme manner than the average male in their propensity to “systematize” rather than “empathize” (Auyeung and Baron-Cohen 2008; Baron-Cohen et al. 2005). Moreover, he proposes that such sexual differences in cognitive processing, and by extension, traits associated with autism, may be related to levels of fetal testosterone, and that the ratio of the lengths of the second and fourth digits, which is lower in males, may serve as an approach to assess exposure to androgens during fetal development (Auyeung and Baron-Cohen 2008). However, experimental validation of this hypothesis, via studies analyzing the association of fetal testosterone levels and the occurrence of autism, is required (Auyeung and Baron-Cohen).

There are a limited number of studies of differences in sex hormone levels in individuals with autism, and no studies of therapeutic interventions involving the use of sex hormones (Anderson and Hoshino 2005). At this time, further research is required to elucidate how sex hormones establish sexual dimorphisms both in the developing brain, producing structural differences, and at the molecular level, resulting in sex-specific differences in gene expression.

Definition

There are numerous reasons why the sexual behavior of people with Autism Spectrum Disorder (ASD) may appear atypical when compared to

the general population. Adolescence is the developmental period when sexual expression emerges for most individuals. In addition to the usual information provided (albeit often inadequately) by parents and school programs, typically developing adolescents rely on friends to learn about cultural norms of sexual behaviors and relationships (Song et al. 2000). Most adolescents with ASD, in contrast, do not develop the close reciprocal friendships that so often lead to the sharing and vetting of important information about sexuality (Murphy and Elias 2006). Thus, they may not have an opportunity to discuss their interests and behaviors with friends and miss the opportunity to hear others' perspectives and may not internalize the full set of social norms. The social differences of people with ASD also increase the likelihood of sexual behavior, knowledge, identity, and experience that differ from typical, mainstream experience, and raise the likelihood of sexual behaviors that are perceived as deviant (Dewinter et al. 2013). Further, while typically developing people may feel the urge to engage in less common sexual behaviors, they are usually influenced by peer perception and social expectations, and are highly attuned to the potential social and legal ramifications of engaging in these types behaviors.

When a person with ASD engages in illegal sexual behavior, the behavior may result from a core characteristic related to the diagnosis, rather than to a sexually "deviant" impulse. The term "counterfeit deviance" is sometimes used in such situations to describe inappropriate behavior rooted in factors other than true deviance (Hingsburger and Griffiths 1986). "Counterfeit deviance" is most often used in the context of inappropriate sexual behavior, in which the observed behavior looks paraphilic but, upon closer examination, was the result of other factors. Stalking often falls into this category. The social challenges associated with ASD may result in a person with ASD missing social cues that indicate their romantic target is not interested, and, because the person with ASD has not perceived these cues, they continue to pursue the person to the point that law enforcement becomes involved (Post et al. 2014). Likewise, a lack of awareness of

social perceptions of behavior or even a lack of concrete understanding that certain things happen in certain places can lead to charges like indecent exposure or public masturbation.

Despite these challenges, it is important to keep in mind that in many ways sexual behaviors in ASD may not differ at all from general population norms. For instance, one investigation of teenagers with ASD found behaviors, interests, and attitudes of those with ASD were largely consistent with those of neurotypical individuals. The only significant difference was that the boys with ASD were significantly more open-minded about homosexuality (Dewinter et al. 2015).

As with any group of people, it is possible for a person with ASD to display a truly deviant sexual interest or drive. It is important to keep in mind, however, that there is no evidence that truly deviant interests or drives occur at a higher rate in ASD than in the general population.

Sexuality and Romantic Relationships Among People with ASD

Kellen Mermin-Bunnell, Maria Canon and
Cristofer Zillo
Yale Child Study Center, New Haven, CT, USA

Definition

A review of the current research on sexual and romantic relationships and behaviors in the ASD population includes recommendations about sexual education for individuals with ASD with the help of their caretakers/teachers.

Historical Background

Autism spectrum disorder (ASD) is characterized by persistent deficits in social communication and interaction as well as restricted, repetitive behavior patterns (5th ed.; DSM-5; American Psychiatric Association 2013). Individuals most often exhibit signs and symptoms of autism in early childhood. However, distinct deficits may not manifest fully until social demands exceed the individual's social abilities (DSM-5 2013). Children with ASD often struggle in school due to low verbal and/or nonverbal intelligence quotients (IQ) and experience difficulty making friends (Lai et al. 2013). Despite these challenges, an increasing number of individuals with ASD have found work, earned the opportunity to attend

college, and formed successful relationships (Newman et al. 2011). Marriage was originally thought to be impossible for almost all individuals with ASD. However, a growing number of people with the disorder, especially those who are high functioning, engage in marriage (Newman et al. 2011).

A growing body of work has found that individuals with ASD often experience sexual desires and participate in romantic relationships (Van Bourgondien et al. 1997; Dewinter et al. 2015; Fernandes et al. 2016; Strunz et al. 2017). Little work regarding this topic has appeared until recently, as research initially labeled people with ASD as sexually immature, asexual, or, in the case of those caught up in legal punishment, hypersexual (Kellaher 2015). Historically, it was thought that individuals with ASD used only masturbation as an outlet for sexual frustrations (Van Bourgondien et al. 1997). Individuals with ASD were seen as more likely to be irritable and aggressive if their sexual needs were not met through self-pleasure, even though these hypotheses were not supported with empirical studies (Van Bourgondien et al. 1997). Additionally, there is a lack of data comparing the sexual and romantic behavior of males with that of females. Both the nature and the frequency of these behaviors should be analyzed. Females with ASD are a highly underrepresented demographic in autism research due to the disparity in prevalence of the disorder between sexes. The rate of ASD is three to four times higher in males than in females (Loomes et al. 2017). There is also minimal research regarding gender dysphoria among those with ASD.

Current Knowledge

Since the recent boom in ASD and intimacy research, perspectives on the matter have changed drastically. Strunz and colleagues found that individuals with ASD participate in romantic relationships more often than not, with 73% of study participants reporting that they had engaged in a romantic relationship. It is important to note, however, that the study only focused on

individuals who did not possess any form of cognitive impairment. Additionally, more than half of the participants who were single stated that human contact was too exhausting for them, expressed fear of not fulfilling a romantic partner's expectations, and/or admitted to not knowing how to find or get involved with a romantic partner. Half of the participants conveyed uncertainty about how to navigate relationships or how to behave when committed to one. (Strunz et al. 2017).

It has been found that individuals with ASD have a greater propensity to be bisexual or homosexual than the general population (Dewinter et al. 2017). Furthermore, people with ASD have a higher frequency of tolerance for homosexuality than that which is found in the general population (Dewinter et al. 2013, 2015; Fernandes et al. 2016). Dewinter et al. (2017) surveyed a large sample of adolescents and adults and found that 18.4% of men with ASD and 43.4% of women with ASD identified as non-heterosexual, while only 9.6% of typically developing men and 13% of typically developing women identified as non-heterosexual. An increased prevalence of gender dysphoria has also been found among individuals with ASD when compared to the rate in the general population. Dewinter et al. (2017) found that 8% of males with ASD and 22% of females with ASD experienced feelings of gender nonconformity; in the general population, 5.7% of males and 4% of females have gender dysphoria. The explanation for the difference in rates of gender dysphoria and non-heterosexuality between the ASD and non-ASD population is as of yet unclear.

Individuals with ASD are disproportionately at risk of becoming victims of sexual assault. Several increased risk factors exist within the ASD population, making these individuals more susceptible to abuse. Some of these risks include social-emotional deficits in understanding their own feelings as well as those of others, dependence on service providers who often have to help in the bathroom where sexual assault could be misconstrued with helping, poor communication, and difficulty identifying sexual assault. Despite the strong evidence for increased risk factors, there is no data to support an increased rate of sexual assault against people with ASD. Parents

reported that approximately 12% of participants with ASD experienced at least one instance of sexual abuse. This number is not significantly different from the general population, which is 6–10% for men and 16–23% for women. Primary reasons that a disparity has not been found are underreporting and stigma, which prevent the uncovering of an increased prevalence of sexual assault against people with ASD as compared to the general population. Sexual assault is often reported by a parent or guardian rather than the victim, and individuals with ASD may not tell their caretakers about their assault or not even understand they have been sexually assaulted. For example, some evidence suggests that the rate of assault is higher among males with ASD than among neurotypical males. Moreover, because ASD presents in vastly different ways for different individuals, it is hard to generally help and educate the population on understanding sexual assault (Sevlever et al. 2013).

Additionally, those with ASD may engage in sexually offending behavior due to their diminished capacity for empathy, poor social reciprocity, and possible sexual frustration (Sevlever et al. 2013). Individuals with ASD may not understand how their actions make others feel or that their actions are inappropriate (Sullivan and Caterino 2008; Fernandes et al. 2016). People with ASD are also less likely to understand or reference another person's emotions when presented with romantic situations and instead tend to refer back to learned social rules and norms (McNaughtan 2019). This could result in the individual with ASD not understanding the effect they are having on their partner's experience. In a 2002 study by Hurlbutt and Chalmers, three high-functioning individuals with ASD were interviewed and asked questions about their life experiences. One participant admitted to scaring off girls he liked by frequently calling them, not understanding that this behavior was a form of harassment (Hurlbutt and Chalmers 2002). It was found that individuals with ASD, but without physical identification explaining their diagnosis, are more likely to engage in inappropriate behavior (Fernandes et al. 2016). One possible cause is that, without ID, others may not understand that socially

inappropriate behavior could be the result of ASD and, therefore, shun rather than support those engaging in the behavior. Additionally, Sevlever et al. (2013) found that individuals with ASD are often legally cited for sexually offending behavior due to their difficulty in discriminating between privately appropriate and publically appropriate behavior, such as masturbation or nudity. Lack of social understanding, for example, in the context of sarcasm and jokes, may also lead individuals with ASD to act out sexually through exposure of genitalia or engaging in unwanted sexual contact with others. These actions frequently result in conflict with the forensic and legal systems, including being charged with sexually related offenses (Sevlever et al. 2013).

Kellaher and colleagues describe the prevalence of deviant sexual behaviors in individuals with ASD, which includes fetishism, pedophilia, and masochism. The behaviors can be grouped into autoerotic behaviors, like transvestism and fetishism, and person-oriented behaviors such as frottage and pedophilia. Of the cases examined, autoerotic behaviors did not lead to legal infractions, as they are not considered taboo. Of those exhibiting person-oriented deviant sexual behaviors, legal ramifications were less likely to occur if authority figures such as administrators or teachers had been understanding of the individual's diagnosis. Kellaher also speculates that the prevalence of sexually deviant behaviors – specifically sadism, transvestism, masochism and fetishism – may be connected to sensory abnormalities related to ASD. These sexually deviant behaviors have a higher chance of being fostered in an individual strongly drawn to certain stimuli, such as the infliction of pain, while in a time of sexual naïvety (Kellaher 2015).

Because of differences associated with ASD, there has been a call to reorganize and reimagine sexual education for those on the spectrum. There is a large difference between the perceived and actual sexual knowledge of individuals with ASD, who were more frequently obtaining knowledge through trial and error than through sexual education (Kellaher 2015). Corona et al. (2016) collected input from parents of children with ASD and found that many believe that the current

sexual education is not adequate. Numerous parents reported that their children still performed inappropriate sexual acts in public, such as touching their own genitals or the genitals of others, after participating in a school-based sexual education program (Corona et al. 2016). Adequate sexual education is essential for controlling these inappropriate public behaviors, improving social deficits that translate to a higher susceptibility to being a victim of abuse, and providing an environment to foster healthy sexual habits (Travers and Tincani 2010). Therefore, sexual education, especially for those with ASD, should encompass topics such as self-awareness, personal hygiene, abuse awareness, self-esteem and assertiveness, stages of romantic relationships and how to maintain them, sexual responses and decisions, partnered sex, sexual anatomy, reproductive rights and health, contraception and STIs, and parenting (Travers and Tincani 2010; Davies and Dubie 2011; Tullis and Zangrillo 2013).

Sexual education curricula for ASD individuals are few and far between. Using the framework from curricula used to educate adults with developmental delays (DD) could provide a start for such programs due to similar difficulties between those with DD and those with ASD. Sexual education curriculums must be flexible to allow for updates, incorporate current research, and adapt to the students' age and mental abilities. Additionally, sexual education not should be limited to strictly teaching the mechanical skills involved but should focus on all levels of social interaction. Sexual education not only should include understanding of sexual interactions, sexual intercourse, and contraception but should incorporate skills in using menstrual products and checking for abnormalities in the body, such as a breast or testicular self-examination. These self-care tasks may require more particular and personalized teaching methods given the absence of readily available environmental signals that many individuals with ASD rely on (Tullis and Zangrillo 2013).

A question important to the design of sexual education for people with ASD is who the most effective sexual educators are and when and where such education should occur (Sevlever

et al. 2013). Someone who is familiar with the strategies that maximize the learning of students with ASD should lead sexual instruction (Davies and Dubie 2011). However, sexual education for individuals on the spectrum should not be limited to ASD experts. Regarding residential programs, there should be systematic training of all staff on how to teach their residents to appropriately express sexual feelings in order to better aid these individuals (Van Bourgondien et al. 1997). Moreover, parents who did not partake in sexual education or who had low sexual expectations for their children were more likely to only address basic sexual topics instead of using a comprehensive approach (Holmes et al. 2016). Not addressing important sexual factors, including but not limited to contraception, sexual abuse, and partnered relationships/sex, increases the risk of victimization and publically inappropriate sexual behaviors (Koegel et al. 2014). Because of this, it is critical that parents and caregivers are provided with appropriate and accurate information and educational strategies to support the sexual development of their children with ASD (Byers et al. 2013).

Future Directions

As knowledge about autism spectrum disorders becomes more vast in the coming years – and those on the spectrum are pushed farther into adult expectations – further opportunity and pressure to seek romantic or intimate relationships will emerge. As more research is conducted regarding the sexuality associated with ASD, the aforementioned reworking of the sexual education system should be considered, as it cannot lag behind other areas of ASD education and programs. Each individual with ASD requires unique and often personalized treatment, but research and surveys could improve personalized planning and public school curriculum regarding sexual and relationship education for those on the spectrum.

Another particular direction of research encapsulated by intimacy and ASD is genetic research. People with ASD are more likely to marry and/or have children with individuals who also have

differences (Newman et al. 2011). Speculation based on the strong evidence for genetic causality of ASD suggests that children born of those who are on the spectrum may also receive a diagnosis, but further studies are required to determine if this is the case. The implications of raising children if one or both parents have ASD and if both the parents and the children have ASD should be studied.

Technological advancements and consumerist economies ensure that education is not the sole source of information in modern day. Recent studies have delved into the accessibility of sexually explicit images accessed via the internet, with half of the adolescent males with ASD sampled having discussed sex on the internet within the 6 months prior to the survey. The vast majority had viewed the images on pornographic websites (Dewinter et al. 2015). Additionally, online dating and social forums provide an impersonal and anonymous environment that individuals with ASD might thrive in. This setting could also provide a medium for victimization (Koegel et al. 2014). Therefore, the effect of media on an ASD individual's perspective on sexuality and romance should be considered and studied. Media usage and its consequences should also be incorporated into sexual education curriculums.

Moreover, the research about romantic relationships within the ASD population has largely neglected to study low-functioning individuals with ASD. A majority of the studies referenced in this paper pertained exclusively to higher-functioning individuals. Current educational advice is also more focused on the higher-functioning population (Davies and Dubie 2011) and should be generalized or modified for the rest of the ASD population. It is important to investigate current sexual education curricula to better understand what kinds of programs work best for all individuals with ASD, both high and low functioning (Tullis and Zangrillo 2013).

Despite large strides in recent research, women with ASD are still consistently underrepresented in study pools, especially with regard to intimate topics. Very few of the studies referenced here included females or equally represented them.

Navigating sexual intimacy and romance would undoubtedly be a different experience for females with ASD and needs to be studied to a further extent.

With regard to all the above topics, the perspective of those with ASD should be considered. Many individuals have a desire to share their own experience in efforts to improve life for others who share the same diagnosis (Hurlbutt and Chalmers 2002). In addition to those who study ASD, the true experts, undoubtedly, are individuals who have personally lived with ASD and through this have developed opinions on how therapies, programs, and interactions can be improved drastically. Therefore, input from individuals with ASD from various age groups should be collected and considered.

Sexuality in Autism

James W. Loomis
Center for Children with Special Needs,
Glastonbury, CT, USA

Definition

Sexuality refers to the physiological processes, behaviors, impulses, and desires associated with reproduction, the genital organs, and mating.

Historical Background

Research has studied sexuality in autism over the last 30 years. Early thinking assumed that individuals with autism were generally asexual or that they expressed their sexuality in inappropriate ways. More recently, there have been a small number of studies examining the sexual behaviors of various samples of individuals with autism or Asperger's disorder, with more attention being paid to males. However, the challenges of studying a highly private aspect of human experience in a group with limited communication skills leave us with only a beginning understanding of how individuals with autism experience their sexuality.

Current Knowledge

There is a wide variation in the sexual functioning of individuals with autism, and so generalizations must be made with care. There are people who experience full sexuality with partners, entering into marriage and having children. There are others who never have any interest in sexual activities.

That being said, research has generally found few differences in the physiology and development of sexual functions between people with autism and others. A majority of individuals with autism, both men and women, demonstrate an interest in sexuality and masturbate or seek sexual stimulation in other ways. For some, particularly individuals with greater developmental challenges, the interest in sexuality may be delayed or may never emerge, but this is the minority. While there have not been extensive clinical studies of sexual functioning, it is thought that most individuals with autism enter puberty at the expected time, evidence the physical changes associated with this development, experience arousal and climax, and are capable of reproduction. Many exhibit behavior challenges and regression during puberty as they adjust to the changes in their bodies.

However, moving beyond the physiological aspects of sexuality, differences are found in the ways individuals with autism experience

attraction and arousal. Social challenges reduce the focus on romantic bonding with others and the power of sexual taboos or regulations. Consequently, for many, sexual fantasies are less likely to focus on an erotic situation with partners, and there is a greater frequency of attractions to non-human contents such as objects, animals, cartoon characters, undergarments, body parts, or particular sensory experiences.

There is also some suggestion in the literature that individuals with autism are more likely to experience homosexuality, bisexuality, or issues related to gender identity. While there is no strong empirical evidence to support this trend, it is consistent with the idea that the social challenges of autism lead to a sexual orientation and gender identity less bound by societal dictates or rules from the family and peer group. Furthermore, with autism, sexuality can develop more independently of relationships to others. For some high functioning individuals, struggles with their sense of gender are closely tied to more general questions about their identity as a young adult – what roles they can fill, how they should act, and what types of relationships they should form.

Challenges to sexual relationships: When trying to engage in sexual activities with partners, individuals with autism encounter several sets of obstacles. Their challenges with social skills, reduced social motivation, and problems following the “hidden curriculum” of social conventions often leave them isolated or withdrawn, the target of teasing or bullying, and without friendships or a peer network. They may not have regular access to and interactions with potential partners. Furthermore, competent courtship or sexual play requires subtle (verbal and nonverbal) communication, knowledge of complex social rules, and well-developed sensory processing, all areas of challenge for most people with autism. Many males experience extreme frustration that they cannot find partners for romantic or sexual relationships. For some of the highest functioning individuals, they are able to maintain friendships with women and to regularly socialize with other adults, yet do not have the skills to effectively engage in the behaviors needed to start a sexual relationship. In our culture, women often have

less difficulty finding partners who are seeking sexual interactions but may encounter a succession of liaisons that only include sexual activities without the establishment of a romantic or committed relationship. With their limited social judgment, some women with autism are vulnerable to engaging with serial partners in a dangerous and promiscuous manner.

Even when individuals with autism are able to find a partner, their experience of sexuality can be out of synch with the relationship. They may not enjoy the sensory aspects of lovemaking, may have difficulty focusing on the pleasure of their partner, or may engage in behaviors not affirming to their partner. The literature written by individuals with autism highlights the challenges of marriage or long-term sexual relationships.

Problems with sexual behaviors: While some individuals with autism experience pleasurable and satisfying sexual activities (autoerotic and with partners) that conform to the rules and expectations of the culture, there are a number of difficulties cited in the literature. One of the greatest concerns of families and caretakers is repetitive, compulsive masturbation for extended periods of time. In some cases, this may entail finding erotic materials on the Internet or calling sexual phone services. With their limited judgment and poor understanding of the implications of their actions, individuals may run up large bills or fall prey to computer viruses. An excessive interest in self-pleasuring sexual activities is most common when the individual is understimulated without the availability of other recreational activities or entertainment (such as for individuals in an institutional setting). Usually, providing alternative leisure activities and teaching them the skills to take advantage of such activities leads to a reduction in sexual self-stimulation.

Difficulties with not being able to effectively stimulate oneself to climax can cause problems. Poor technique can lead to hypermasturbation, or repetitive, nonorgasmic self-stimulation, as the individual does not experience the release and resolution of orgasm. In rare cases, individuals engage in atypical masturbatory activities with objects or materials that lead to self-mutilation or injury. There are also many cases where

psychotropic medication impacts sexual arousal or the ability to reach climax, and this can interfere with satisfying sexual practices.

Another key area of challenge relates to a lack of modesty. People with autism may not experience discomfort in front of other people when undressed, engaging in self-stimulation, looking at sexual materials, or talking about sexual topics. For some, self-stimulating sexual behaviors may occur compulsively in certain situations or in response to particular sensory experiences, even when they are in a public setting. Additionally, touching the genital area or other sexual gestures may be exhibited as part of a stereotypy without sexual stimulation being experienced. Whatever the motivation, these sexual behaviors in public lead to alienation of peers and others, trouble with school and community authorities, and embarrassment for family members.

Sexual impulses can also lead to inappropriate contact with strangers or people in the community. Some individuals become attracted to and stimulated by women's hair, legs, or other body parts. They may stare at people with the desired attribute or even attempt to touch them. Males with autism, accustomed to getting hugs from teachers and other caretakers when younger, may seek out hugs from women as an adolescent or adult and become noticeably aroused by such contact. Some of these behaviors may be more driven by sensory seeking than by sexual arousal, but they appear to be sexual violations and are responded to as such, leaving the individual vulnerable to extreme sanctions.

Sexual behaviors performed by individuals with autism in public are often misunderstood to be paraphilias or sexual disorders. They can be viewed as exhibitionistic when they disrobe, even though they are undressing because of sensory issues and a lack of understanding of social rules around nudity, rather than because it is sexually arousing. Their focus on objects or body parts can be described as fetishistic. An interest in looking at images of children can be seen to be pedophilic. While there are high functioning individuals with autism who present true paraphilias, careful assessment of these behaviors indicates that they are more frequently the product of

sensory processing issues, a lack of understanding of social rules, and deficits in perspective taking. As with any inappropriate sexual conduct, they require a strong response that will prevent their occurrence. Yet, unlike true paraphilias, when these behaviors are based in autistic functioning, they are responsive to education and behavioral intervention.

In severe cases, sexual interests and practices can lead to criminal behaviors such as stealing objects for sexual stimulation (e.g., women's undergarments), illegally using credit cards to access pornography, or making inappropriate sexual advances. Staring at or touching strangers in public can be understood to be stalking or sexual assault. There is a particularly troubling trend of male individuals, searching for erotic materials on the Internet, visiting child pornography sites. These individuals may have no capacity or desire to prey on children yet get caught and arrested when detected by law authorities. When sexual behaviors are viewed to be criminal, individuals have to deal with a justice system that often does not understand autism and can deal harshly and destructively with individuals.

In all these cases, thorough assessment of the pattern of behavior is needed. For example, in one case, a young man was making detailed, sexually threatening comments to women using seemingly precise jargon and terminology to describe what he intended to do. A comprehensive evaluation of his pattern of arousal and sexual knowledge revealed that he knew very little about sexuality and experienced no sexual arousal. He was just mimicking phrases he had heard and was reinforced by the reaction he received.

A final challenge related to sexuality is the vulnerability of people with autism to predatory individuals. With their difficulties with perspective taking, understanding social rules, judging intent, and anticipating outcomes, individuals are easy targets for people who are sexually abusive, assaultive, or predatory. This is particularly true for females. It is important to provide education and necessary levels of supervision to prevent victimization.

Facilitating sexual development: Building a positive sexual adjustment in people with autism

requires careful monitoring, individualized sex education, and behavioral intervention when problems occur. Caregivers need to consider all the situations confronting the individual and ensure that they will not be vulnerable to predators, exposed to sexual materials, or likely to act inappropriately. Access to the Internet or phone lines should be controlled. The amount of hugs and physical contact permitted with teachers and caregivers should be adjusted and eliminated when the child is in preadolescence. As the child develops and is more able to be independent, it is essential to teach him the skills he will need to handle potential sexual impulses or threats and remain safe and appropriate.

Effective sex education is the best way to prevent sexual problems. It should be provided as soon as the child exhibits sexual interest or behaviors and reviewed and revisited on a regular schedule. The information should be geared to the individual's needs and his ability to understand. For the people with the greatest level of challenge, this instruction might just focus on rules about acceptable sexual behaviors in public and in private, and on appropriate and inappropriate touching. It may be necessary as well to teach the individual effective ways to stimulate himself/herself and define where and when this can occur. With higher functioning people who are seeking sexual partners, education should cover more detailed information about sexual functioning, sexually transmitted diseases, pregnancy, and sexual abuse/assault. Depending on the level of understanding, there should also be instruction about dating relationships and the process of courtship. Teaching should be delivered in a way that is effective for people on the autism spectrum. This includes emphasizing rote instruction, using visual context cues and materials, providing rehearsal with scaffolded supports, fading prompts as they are no longer needed, and including generalization training. Teaching techniques known to be effective with individuals with autism, such as social stories, rule cards, priming, and social autopsies, should be utilized to ensure effective instruction.

When sexual problems occur, careful assessment is warranted. For many difficult situations, additional education may be all that is needed.

When problems persist, the incidents should be tracked and studied through a functional behavior analysis in order to identify triggers and situations that must be avoided, to teach needed skills and alternative responses to the inappropriate conduct, and to ensure that the target behaviors are not being inadvertently reinforced. As noted above, designing the most effective response may require careful assessment of the individual's sexual knowledge and pattern of arousal, sensory processing factors, and other secondary factors.

Future Directions

Research into sexuality and autism is just beginning to systematically assess the sexual functioning, development, interests, and behaviors of people on the autism spectrum. This work should be expanded to larger, more representative samples and should examine differences across gender, age, cognitive ability, level of autism, and other key variables. Particular attention should be paid to problematic sexual conduct/victimization and ways to prevent and effectively treat it. There is a developing literature on sexual education for people with autism, and this needs to expand to provide families and schools access to effective teaching materials that apply to a wide range of individuals. At the level of social and behavioral research, we need to better understand how high functioning individuals with autism can remain more integrated with peer groups and develop the skills needed for dating, courtship, and maintenance of sexual relationships.

SHANK 3

John D. Murdoch and Michael F. Walker
Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Synonyms

DEL22q13.3 (Entrez Gene, OMIM, Uniprot); KIAA1650; Proline-rich synapse-associated protein 2; PROSAP2; PSAP2; SCZD15; SPANK-2

Definition

SHANK3, the gene encoding the protein *SH3 and multiple ankyrin repeat domains 3*, belongs to the SHANK family of genes; the other members are SHANK1 and SHANK2. The members of the

SHANK family of genes are scaffolding proteins, comprising multiple domains, that are found in the postsynaptic density and connect membrane proteins, such as neurotransmitter receptors (e.g., NMDA-type and metabotropic glutamate) and ion channels, to the actin cytoskeleton and to intracellular signaling pathways. They are actively involved in synapse formation and dendritic spine development (EntrezGene, Uniprot, Durand et al. 2012). SHANK3 is located on chromosome 22.q13.3 and the canonical verified isoform consists of 1741 amino acids, with at least one other isoform (Uniprot).

SHANK3 is the site of a recurrent chromosomal breakpoint within 22q13.3 (Bonaglia et al. 2006), leading to a 22q13.3 deletion syndrome. Deletions and other disruptions in 22q13.3 were subsequently linked strongly to autism (Durand et al. 2007). Recent clinical reviews have stated that 22q13 abnormalities are estimated to be involved in roughly 1% of all autism diagnoses (Abrahams and Geschwind 2008; Buxbaum 2009). Functional studies also demonstrate the severe effects of SHANK3 disruption; mutations in SHANK3 were recently shown to affect dendritic spine development (Durand et al. 2012). A mouse SHANK3 knock-out (in which both copies of a gene have been removed) also demonstrated compulsive and repetitive behavior and social impairments, reminiscent of an autism phenotype (Peça et al. 2011). SHANK3 is one of a handful of genes thought to be conclusively associated with ASD. It has also recently been linked to schizophrenia (Gauthier et al. 2010).

ProSAP2

Definition

Shank is a super scaffolding protein located at the glutamatergic synapses. Through interacting with other synaptic proteins, Shank plays a key role in orchestrating signalling molecules and spine morphology at the post-synaptic density. Shank protein is encoded by Shank 1, Shank 2, and Shank 3 genes. It consists of five important domains, including N-terminal ankyrin repeats, Src homology domain3 (SH3), PSD-95/Dlg/ZO-1 domain (PDZ domain), proline-rich region, and C-terminal sterile alpha motive. Meta-analysis shows that up to 1% of autism spectrum disorder

(ASD) patients have mutations in Shank genes. In particular, Shank 3 has been heavily studied. Patients with Shank 3 mutation are associated with more profound cognitive impairment, and it has been proposed that Shank 3 as the target of genetic screening in ASD. Shank 3 partial gene-deletion or gene-knockout rodents show abnormal social communication, repetitive rituals, and self-injurious behavior. Long-term potentiation, a process that is believed as the physiological basis of learning and memory, are impaired in these animals. Taken together, perturbation of Shank protein may lead to synaptic dysfunction, which has been proposed as the common mechanism among ASD heterogeneous etiologies.

Shaping of Behavior

Anna M. Krasno
The Gevirtz School, UC Santa Barbara Koegel Autism Center, Santa Barbara, CA, USA

Definition

Shaping of behavior is a behavior modification technique that rewards successive approximations

to a desired target behavior. For individuals with autism, shaping can be used to teach new behaviors. The procedure involves defining what the target behavior should be and then choosing which initial response to reinforce. The initial response to reward should be something that the individual exhibits that is related to the target behavior. Approximations to the desired behavior are differentially reinforced as the shaping procedure is implemented. Each successive approximation that is closer to the target behavior is reinforced, while reinforcement is withheld for earlier approximations in order to continue moving toward the target behavior. For example, shaping was initially used to teach children with autism expressive words. Rather than only providing a reward when a desired word was produced, differential speech attempts that become closer and closer to the target word were rewarded in order to shape the target word and increase the individual's motivation to speak. Newer approaches found that shaping usually is not necessary for producing speech in nonverbal children, and reinforcing verbal attempts may be more effective (Koegel and Koegel 2012).

Shared Book Reading with Preschoolers with Autism

Jaclyn M. Dynia¹ and Veronica P. Fleury²

¹Crane Center for Early Childhood Research and Policy, The Ohio State University, Columbus, OH, USA

²Florida State University, Tallahassee, FL, USA

Definition

Shared book reading, also referred to as “interactive book reading,” includes a variety of strategies that adults use when reading to children. Shared reading activities are commonly conducted in small groups or in 1:1 arrangement. During shared reading, adults use a variety of strategies to actively engage young children in the act of reading and storytelling to promote children's language and early literacy skills. Systematic reviews of the evidence base on shared reading interventions reveal potentially positive effects on phonological processing and early reading/writing skills with mixed effects on comprehension and language development (US Department of Education). The majority of studies included in the evidence base for shared reading interventions involve typically developing children and children from at-risk populations. Within the past decade, researchers have extended the application of shared reading interventions to children with disabilities, specifically those with autism spectrum disorder (ASD).

Historical Background

Reading Readiness Versus Emergent Literacy

Reading instruction for children with developmental disabilities has historically been absent from educational programming or severely lacking in quality (e.g., sole focus on sight word instruction; Spector 2011). Excluding individuals with severe disabilities from reading instruction was justified according to the reading readiness approach to learning which suggested that

students' readiness to learn and their physical status were fundamental to beginning literacy instruction. Fundamental factors believed to be responsible for school failure or success included physical readiness (visual acuity, hearing, intellectual readiness (measured by IQ and "reading readiness" tests) and personal readiness indicators such as social maturity, language readiness skills, and perceptual readiness (Williams 1953). According to the reading readiness model, many children with developmental disabilities would not receive literacy instruction on the basis that they were not "ready," and formal reading instruction was not included as part of the educational plan. Within the reading readiness paradigm, literacy development fell under the domain of formal schooling; parents and early childhood educators had little involvement or influence in children's reading development. Work initiated by Marie Clay (e.g., Clay 1975) challenged this paradigm by arguing that children's early experiences with informal literacy activities support reading development. Whereas the reading readiness approach creates a clear distinction between pre-reading and reading, the emergent literacy paradigm conceptualizes literacy acquisition as a continuum beginning at birth. That is, children's literacy development begins long before children start formal instruction in elementary school. Young children gain a number of foundational skills that support future reading achievement through their informal interactions with literacy materials even though they are not able to read or write in the conventional sense (Whitehurst and Lonigan 1998). Accordingly, researchers studying emergent literacy have focused on understanding how children's environments and experiences support the development of skills, knowledge, and attitudes related to reading development.

Adults play an instrumental role in supporting young children's early literacy skill development by creating literacy-rich environments. The creation of supportive literacy environments includes (a) adult-directed activities that expose children to literacy, such as reading to children, (b) opportunities for children to independently explore books and writing instruments, and

(c) structuring the setting in a manner that allows both exposure and access to these aforementioned opportunities (e.g., displaying environmental print, creating book areas, writing centers; Smith and Dickenson 2002). Literacy-rich early childhood environments give young learners ample opportunities to engage in meaningful literacy activities. By engaging in literacy activities, by observing others engage in literacy activities, and through direct teaching, children gradually develop knowledge about language, print, and literacy (Teale and Sulzby 1986). It is now understood that reading, writing, and oral language develop in a complementary way. Adults play an important role in interacting with children and structuring their environment in ways that can help them learn these skills long before they begin formal schooling.

Literacy Development in ASD

The rate of reading improvement for individuals with autism spectrum disorder (ASD) is significantly slower than that of students with learning disabilities (Wei et al. 2011). The majority of literacy research that has been conducted with this population is focused on conventional reading skills, such as decoding, fluency, and comprehension (Huemer and Mann 2010; Mayes and Calhoun 2003; Nation et al. 2006). Although the research on early literacy development for children with ASD is rather limited (Westerveld et al. 2016), findings from emerging research suggest that many children with ASD demonstrate early signs of reading difficulty during the preschool years (Fleury and Lease 2018; Westerveld et al. 2017). Westerveld et al. (2017) found that 40–75% of preschool children with ASD performed within expected range in code-focused emergent literacy skills (i.e., alphabet knowledge, print knowledge, phonological awareness) compared to only 15% scoring within the expected range for meaning-focused emergent literacy skills (i.e., vocabulary knowledge, listening comprehension). Upon closer examination of specific code-focused component skills, children with ASD are particularly strong in one particular aspect of code-focused skills: alphabet knowledge. Multiple research groups have replicated

this finding of alphabet knowledge being a relative strength in young children with ASD (Davidson and Ellis Weismer 2014; Lanter et al. 2012; Westerveld et al. 2017). Other aspects of code-focused skills – print concept knowledge and phonological awareness – remain relatively weak for this group of children (Davidson and Ellis Weismer 2014; Dynia et al. 2014; Lanter et al. 2012). The marked variability of emergent literacy performance across studies is particularly noteworthy and appears to relate to language ability, nonverbal cognition, and autism symptom severity (Dynia et al. 2014; Westerveld et al. 2017).

Generally, children with ASD have considerably greater difficulty acquiring meaning-focused skills – the extent to which children understand language. Weakness in the ability to draw meaning from literacy and language is a consistent finding across studies examining emergent literacy profiles for young children with ASD (Davidson and Ellis Weismer 2014; Westerveld et al. 2017). This may not be surprising given the strong correlation between language ability and reading comprehension (Huemer and Mann 2010; Mayes and Calhoun 2003; Nation et al. 2006). It is well established that children's vocabulary knowledge as well as the ability to comprehend and produce language in discourse contributes to reading achievement (Justice and Sofka 2010; Lucas and Norbury 2018). Delayed verbal language is most commonly the first concern reported by caregivers of young children with ASD (Ozonoff et al. 2010). Most young children with ASD develop language later than their typically developing peers (Tager-Flusberg et al. 2005), and although it is currently estimated that between 75% and 90% of children with ASD eventually develop speech (Rogers 2006), they continue to struggle with pragmatics, often referred to as the social aspects of language (Leekam 2007; Tager-Flusberg and Joseph 2003). Difficulties in both language development and the broader domain of social communication have a negative impact on reading comprehension (Lucas and Norbury 2018). Given that social communication problems are a core feature of ASD, it is likely

that many children with ASD will experience reading comprehension failure when presented with school activities in which they are expected to read for meaning.

Shared Book Reading Activities

Experts advocate that early childhood special education programs include emergent literacy instruction as part of the curriculum (Carta et al. 2015) to support children's future reading achievement. A common literacy practice valued by educators and early childhood professionals is reading aloud to children. Reading books to children gained popularity during the 1980s in large part because early childhood policy makers publicized that reading aloud was an excellent, developmentally appropriate instructional practice (Bredenkamp 1986) and several research efforts focused on the topic of parent-child book reading in the home environment (e.g., Heath 1982; Teale and Sulzby 1986). Reading aloud to children emerged as a key facet of family literacy programs and the central focus of several public library outreach efforts (e.g., the Carnegie Library's Beginning to Read program, Reading is Fundamental, Washington Learning Systems [see Segel and Friedberg 1991; <http://www.rif.org/>; <http://www.walearnin.com>]). As a result of these efforts, adult-child shared reading practices (a parent reading a picture book with a toddler or a teacher reading a book to a class of preschoolers) gained popularity and continue to be widely recommended to promote language and other skills related to early literacy development.

The benefits of adult-child shared reading practices on children's language development are based on the premise that book reading allows children to hear adults use rich language and children are then provided ample opportunities to practice using language. Research conducted in the past few decades has stressed that the quality of book reading is more important than the quantity of book reading (e.g., Scarborough and Dobrich 1994). The manner in which children are read to affects their engagement during book readings and what they take away from the experience. A situation in which an adult simply

reads the text on the page positions the child as a passive listener, rather than an active participant in the reading. Compare this to a book reading interaction that involves the adult describing illustrations and asking the child questions about what he or she sees and understands about the story. In this second scenario, the child has the opportunity to and is expected to engage with the text. The child becomes an active participant with the adult, the book, and the entire process of reading. Through quality adult-child shared reading interactions, children not only gain access to a variety of books but are also provided opportunities to develop a number of emergent literacy skills, specifically oral language.

Current Knowledge

Children with ASD may have difficulty fully participating in shared book reading due to deficits in social communication that are characteristic of the disorder (Fleury and Schwartz 2017; Kluth and Chandler-Olcott 2008). Shared book reading requires that children are able to sustain social interaction regarding a particular topic (the book), including asking questions or making comments about what they notice, which can be challenging for many children with ASD due to their difficulties with social communication (Dawson et al. 2004; Tager-Flusberg and Joseph 2003). An important, but less obvious, difficulty that underlies social communication is joint attention, the visual sharing of attention with a social partner in reference to an object of event of mutual interest (Carpenter et al. 1998). Young children with ASD demonstrate lower levels of joint attention compared to typically developing children and age-matched peers with Down syndrome (Adamson et al. 2004). Because the design of many literacy activities relies heavily on social and communication ability, children who lack basic skills in these areas will have difficulty participating in, and benefiting from, these activities without instructional support (Kluth and Chandler-Olcott 2008).

Home Literacy Environment

Shared book reading during the emergent literacy stage of reading development can occur both in the home and at school. In the home, shared book reading frequency is an important aspect of the home literacy environment. Two studies have examined the home literacy environment of preschoolers with ASD. Lanter et al. (2012) found that caregivers of 41 preschool-aged children with ASD engaged in frequent book reading with their child starting at a young age. However, Dynia et al. (2014) found that 35 children with ASD participated in shared book reading less frequently than a matched sample of 35 typically developing children. Further, more frequent shared book reading was related to higher alphabet knowledge for both the children with ASD and their peers. One study that included 41 school-aged children with ASD found that children with ASD and concomitant language disorder participated in more frequent shared book reading than children with ASD and age-appropriate language skills and children who were typically developing; however, the shared book reading sessions were shorter in duration (Lucas and Norbury 2018).

Engagement During Shared Book Reading

Another set of studies has focused on children with ASD's behavior and engagement during shared book reading. When children with ASD participate in shared reading, they attend to the activity for less time compared to their peers (Watson et al. 1996). For instance, Thompson et al. (2018) measured the eye-tracking behavior of ten minimally verbal children with ASD aged 5–8 years old while reading an e-book and compared this eye-tracking performance with children who were typically developing. The children with ASD only attended to the e-book for approximately half of the time that it was presented and when they did attend to the e-book, they were minimally attentive to the literacy concepts (e.g., print). Similarly, Fleury and Hugh (2018) found that preschoolers with ASD ($n = 17$) looked at the book less and demonstrated more non-engaged behaviors during shared book reading with their caregivers than

their typically developing peers. Finally, one study by Bean et al. (2019) examined 22 children with ASD's book reading orientation during a whole-group book reading in a preschool classroom and found that children with ASD were less engaged during whole-group book reading than children with developmental language delay and their typically developing peers. Further, book reading orientation was found to be a significant predictor of gains in emergent literacy skills.

Shared Book Reading Interventions

There have also been several examinations into shared book reading interventions with preschool-age children with ASD. One series of studies has examined the Reading to Engage Children with Autism in Language and Learning (RECALL) dialogic reading intervention for children with ASD (Whalon et al. 2013). RECALL combines dialogic reading strategies and behavior supports for children with ASD (e.g., time delay, direct models, visual supports). Whalon et al. (2015) examined RECALL led by an interventionist with a pair of children (one child with ASD and a participating typically developing peer). Participation in RECALL, which was designed to facilitate joint attention during shared book reading, prompted more correct responses to fact and inference-based questions about the text and resulted in increased reading comprehension for the children with ASD. Parent-implemented RECALL has also been examined in a systematic case study with caregiver-child dyad (Whalon et al. 2016). Results indicated that the caregiver could implement RECALL with integrity and the child with ASD increased their spontaneous correct responding. Similarly, in a study by Fleury et al. (2014), the researcher engaged in one-on-one book reading sessions using a variety of dialogic reading question prompts (e.g., recall, open-ended questions, wh-questions) during shared book reading. Results indicated that all three children with ASD (ages 4–5 years old) participated in longer book reading sessions during the dialogic reading intervention sessions. In another study by Fleury and Schwartz (2017), paraeducators implemented one-on-one book

reading sessions with nine preschoolers with ASD. During these sessions, the children had higher levels of participation during dialogic intervention sessions as well as increases in book-specific vocabulary. The effect of a dialogic reading intervention using technology was examined for four preschoolers with ASD (Grygas Coogle et al. 2018). Results indicated that dialogic reading, using traditional books and technology-enhanced books, was a promising intervention for increasing the vocabulary skills of children with ASD. In a large study on the effects of different emergent literacy interventions, Hudson et al. (2017) examined the effects of an interactive book reading intervention in comparison to a phonological awareness intervention for 133 preschoolers with ASD. Results indicated that children with ASD had significantly greater gains in vocabulary and listening comprehension after participation in the interactive book reading intervention compared to the phonological awareness intervention and business as usual.

Finally, Boyle et al. (2019) completed a meta-analysis of 11 shared book reading interventions for children with ASD. The interventions in the meta-analysis were implemented with preschool- and school-age children with ASD. The six preschool interventions included studies reviewed above (Fleury et al. 2014; Fleury and Schwartz 2017; Whalon et al. 2015; Whalon et al. 2016) and two unpublished dissertations (Vogler-Elias 2009; Zimmer 2013). Results from the meta-analysis showed that shared book reading has positive effects on expressive language and listening comprehension for children with ASD.

Future Directions

Given that the findings on the frequency of shared book reading in the home by children with ASD is mixed, more studies are needed on the types and frequency of literacy activities that children with ASD are experiencing in their homes. In addition, more research is needed on whether the home literacy environment is related to

children with ASD's emergent literacy skills. Further, based on eye-tracking and observational measures, children with ASD seem to be less engaged during shared book reading than their typically developing peers. However, despite the mixed findings on shared book reading frequency and the limited engagement displayed during shared book reading, shared book reading interventions have found positive effects for children with ASD. This suggests that traditional measures of engagement may not be adequately capturing what it means to be engaged for children with ASD. Future studies should examine alternate ways of assessing engagement during shared book reading for children with ASD. As for shared book reading interventions, most of the extant literature is based on studies using single-subject design and small sample sizes. Future research should aim to include larger group design studies including rigorous randomized controlled trials.

(e.g., “Where do you think he will look next?”). When parents scaffold children’s language during shared storybook reading, it becomes a context that can facilitate language development across all ages. Shared storybook reading interventions focus on teaching adults (i.e., parents, teachers, or other caregivers) scaffolding strategies to support language, emergent literacy, and social engagement during the shared storybook reading context. Scaffolding strategies support increased responsiveness to children’s communication attempts and engagement during shared storybook reading. The adult’s role shifts over time as the child gains skills and is able to take on a more equal role during the shared storybook reading (Kaderavek and Sulzby 1998).

Shared Storybook Reading

Dawn Vogler-Elias
Communication Sciences and Disorders,
Nazareth College, Rochester, NY, USA

Definition

Shared storybook reading is a naturalistic and interactive routine in which an adult and a child engage in dialogue and share joint attention on a storybook. During shared storybook reading, children are exposed to both oral and written language at the same time (Ezell and Justice 2005) because children both see and hear the words during the interaction. This routine promotes the development of language and social engagement (Kaderavek and Justice 2002), which are two of the core deficit areas for children with ASDs. Children are exposed to shared storybook reading early in life; many parents report reading to children by 6 months of age (Catts and Khami 1999). Many parents naturally scaffold their child’s development by gradually increasing the cognitive and language expectations during shared storybook reading to match children’s growing abilities (Catts and Khami 1999). For example, toddlers can learn to turn the pages in a book or identify new vocabulary words, whereas older children might learn to make inferences (e.g., “How do you think this boy feels?”) or predictions

Historical Background

Historically, children with disabilities have had reduced access to emergent literacy activities like shared storybook reading when they were not perceived to demonstrate signs of literacy readiness (e.g., the ability to comment about pictures in a book, the ability to answer questions during a story, the ability to sit still for an entire storybook). Children with disabilities begin their school careers with less than one-half the exposures to print as their typical peers (van Kleeck et al. 1997; van Kleeck and Vander Woude 2003).

Children with autism spectrum disorders may have unique risks for reduced exposure to emergent literacy activities, such as shared storybook reading. Firstly, children with ASDs are at risk for difficulty with literacy because literacy is a language-based skill (Catts and Khami 1999) and children with ASDs have difficulty acquiring language. Secondly, caregiver perceptions and practices (Koppenhaver et al. 1991) may contribute to reduced opportunity for literacy exposure. Caregivers may underestimate the abilities of children with disabilities because the children have been labeled as having delays and difficulties (Koppenhaver et al. 1991). In particular, parents of children with ASDs may feel overwhelmed by their child’s behavioral needs or resistance to social interactions. Furthermore, parents of

children with developmental disabilities often devote large portions of the day meeting educational, therapeutic, and medical needs, leaving little time for “extra” activities related to emergent literacy. It is important to recognize that parents of children with ASDs will likely require support to engage in early literacy experiences with their children.

Rationale or Underlying Theory

Children with disabilities have historically had reduced opportunity to participate in emergent literacy activities, which are the building blocks to later literacy achievement. The *interactive to independent* model of literacy development (Kaderavek and Rabidoux 2004) proposes the access to literacy for individuals with atypical communication. The model includes five levels of achievement drawn from the social interaction, participation, and situated pragmatics theories of language and literacy development. Vygotsky’s social interaction theory (Vygotsky 1978) suggests that literacy development is a product of children’s supportive social interactions surrounding literacy. Beukelman and Mirenda’s participation theory (Beukelman and Mirenda 1998) stresses the importance of removing barriers to literacy for individuals with disabilities. Finally, the situated pragmatics theory (Duchan et al. 1994) expands the definition of literacy contexts by stressing the importance of developing goals that allow children to participate in naturally occurring contexts. In the context of the *interactive to independent* model, literacy is not a static skill requiring achievement of specific predetermined criteria before moving onto more advanced steps. Instead, literacy is a dynamic skill made up of several smaller sets of subskills that can be achieved in a nonlinear fashion. The model focuses on five levels of development as children move from emergent to conventional literacy. The first level focuses on joint attention and responsiveness during early literacy interactions by helping the child maintain focus on storybooks, teaching the parent strategies to increase engagement, and increasing the duration of shared

literacy experiences. The second level focuses on balance and turn taking by helping the parent build on the child’s communicative attempts to increase the child’s communicative repertoire surrounding literacy materials. The first two levels of this model have a pragmatic focus in that they prioritize the social aspects of shared literacy experiences, such as turn taking, joint attention, and acceptance of a range of communicative behaviors. The third level of the model begins to move toward conventional literacy by helping the child to increase emergent literacy skills, such as print awareness, phonological awareness, and metalinguistic awareness. The fourth and fifth levels represent movement toward conventional independent literacy, which is defined as a complex language-based skill that involves the ability to read and write. Specifically, the fourth level focuses on achievement of conventional literacy with social support, whereas the fifth level targets the achievement of full conventional literacy without social support (i.e., independent literacy achievement).

Goals and Objectives

The long-term goal of shared storybook reading interventions is to increase literacy opportunity for children with autism spectrum disorders, thus, increasing their opportunity to participate in a literate society. The objectives of shared storybook reading interventions focus on increasing active participation during in shared storybook reading exchanges. Objectives should be child-centered, individualized, and measurable. Justice and Pence (2005) have suggested three features that are essential to effective shared storybook reading interactions: parent sensitivity and responsiveness, child engagement, and repeated reading. The first feature, parent sensitivity and responsiveness, refers to parents who allow children time to respond and show they value child contributions to the interaction. Behaviors of sensitive and responsive adults include observing, waiting, listening, and being face to face with the child. The second feature, child engagement, is facilitated by allowing the child to participate

during the storybook reading. Child participation might include labeling pictures, commenting, and asking questions. Children are more likely to be engaged when they are allowed to set the pace of the interaction. The third feature, repeated reading, allows for increased familiarity and facilitates vocabulary learning. These three features are ways for adults to intentionally scaffold language and engagement during shared storybook reading, thus, moving children to higher levels of performance within the interaction. Another tool, the Kaderavek-Sulzby Bookreading Observational Protocol (KSBOOP) (Kaderavek and Sulzby 1998), can be utilized to assess areas of strength and need during parent-child shared storybook reading exchanges, including parent scaffolding behaviors, child language attempts, and other variables that are contributing to the success of the interaction.

Treatment Participants

Shared storybook reading is an intervention context appropriate for any child, including children with autism spectrum disorders.

Treatment Procedures

Interventions using shared storybook reading focus on teaching adults scaffolding strategies to support language, emergent literacy, and social engagement. These strategies include teaching adults ways to increase responsiveness to children's communication attempts and support engagement during shared storybook reading. The adult's role shifts over time as the child gains skills and is able to take on a more equal role during the shared storybook reading (Kaderavek and Sulzby 1998). Specific strategies include ask WH questions, repeat or recast what the child says, praise and encourage, follow the child's interests or lead, ask open-ended questions, expand what the child says, use attention getters.

Often, the focus of shared storybook reading interventions is to change adult behaviors. That

said, it is important to note that some parents of children with disabilities are already responsive to their children's needs and already adjust their behavior and language accordingly. For example, Justice and Kaderavek (2003) analyzed the shared storybook interactions between 11 preschoolers with language impairment and their mothers. They found that some children with language impairment and their mothers often shared topic control and balance of contributions (although some had a more unequal experience), suggesting that interventions targeting strategies during book reading interactions should be well designed such that they do not decrease positive back-and-forth interactions that are already present in parent-child interactions. In other words, shared storybook interventions should enhance and encourage strategies that parents may already be doing as well as teach them new skills to facilitate language and social engagement.

Efficacy Information

Shared storybook reading contributes to early language and literacy development (Ezell and Justice 2005). Shared storybook reading interventions have been effective at increasing vocabulary development, social engagement, and emergent literacy awareness in at-risk groups, including children living in poverty (Whitehurst et al. 1994a, b) and preschoolers with language impairment (Crain-Thoreson and Dale 1999; Crowe et al. 2000). Clinicians, teachers, and parents were successful at learning to increase strategies to support children's language, social engagement, and emergent literacy skills during shared storybook reading.

To date, only one case study has examined the use of shared storybook reading as an intervention context for children with ASDs. Bellon et al. (2000) examined the use of scaffolding strategies during a clinician-implemented shared storybook reading intervention for a preschooler with high-functioning autism. A seven-week intervention resulted in an increase in the preschooler's spontaneous speech. This preliminary study indicated that shared storybook reading may be an effective

intervention context for young children with ASDs. Shared storybook reading has not yet been explored using a parent-implemented intervention paradigm for preschoolers with ASDs, although a number of other parent-implemented interventions have successfully been examined in children with ASDs.

Outcome Measurement

Outcome measures for shared storybook reading interventions include measures of parent behavior, child behavior, and parent-child variables. Parent focused measures include measuring changes in rate and frequency of scaffolding strategy use. Child focused measures include measuring changes in children's language (e.g., vocabulary measures, mean length of utterance) or emergent literacy skills (e.g., formal measure of phonological awareness and emergent literacy). Parent-child variables attempt to measure changes in social interaction, such as turn-taking ratios or duration of interaction.

Qualifications of Treatment Providers

Interventionists with specific expertise in shared storybook reading interventions include speech-language pathologists and educators.

Sheltered Employment

David J. Krainski
 Vocational Independence Program, New York
 Institute of Technology, Central Islip, NY, USA

Definition

Sheltered employment refers to segregated programs designed to help individuals with disabilities who are not able to work in a competitive employment setting. Sheltered workshops, day treatment, and work activity centers are examples of sheltered employment programs. Usually, sheltered employment programs are run by private, not-for-profit organizations that receive funding through state and federal sources (Kregel and Dean 2002).

Historical Background

Sheltered employment programs can typically be categorized into two types: extended employment and transitional employment. Extended

employment placements are designed to allow the individual the opportunity to utilize his/her abilities to work and earn money in a segregated workshop setting. In transitional employment settings, the individual is provided with training in a segregated setting in order to develop skills that would be necessary to be successful in an integrated employment setting (Kregel and Dean 2002). However, as Taylor notes in 2002, only about 3.5% of individuals in sheltered employment move on to work in competitive employment settings. Taylor also notes that individuals working in a sheltered setting earn significantly less per week than their counterparts working in competitive employment.

The success rate of sheltered employment settings has often been questioned by critics who state that individuals in these settings are not provided with significant employment outcomes and are isolated which contributes to lowered expectations in the workplace and can spur negative attitudes from the rest of the community (Kregel and Dean 2002).

In response to the criticisms of sheltered employment, the U.S. Department of Education's Rehabilitation Services Administration changed the regulations that govern State Vocational Rehabilitation Programs in January of 2001. This change redefines the term "employment outcome" to mean an individual working in an integrated setting (Wehman et al. 2003). No longer would a sheltered, segregated setting be an acceptable, final employment outcome for an individual with a disability.

Current Knowledge

Since sheltered employment is no longer an acceptable final employment outcome for an individual with a disability, many individuals are placed into supported employment programs as an alternative (Kregel and Dean 2002). Individuals may still be placed into a sheltered employment settings as long as the goal is for the individual to build skills and gain experience in order to move into competitive, integrated employment.

Sheltered Workshops

Susan Luger
Susan Luger Associates, New York, NY, USA

Synonyms

[Supported employment](#)

Definition

A sheltered workshop is a self-contained workplace that offers a supportive and protected work environment for people with disabilities. Sheltered workshops are funded by a combination of public vocational and rehabilitation programs and contracts from businesses. Workshops are private not-for-profit corporations. Each workshop must have a special certificate from the Department of Labor. The goal of a sheltered workshop is to provide meaningful vocational experience and job skills for

people with disabilities who cannot find work elsewhere. Employees receive payment; however, their hourly pay is usually below the market rate for similar work in private industry. The workshop may also provide such related vocational rehabilitation services as job interview training.

Description

The Short Sensory Profile (SSP; McIntosh et al. 1999) is a caregiver report questionnaire used

in research and clinical settings to measure sensory processing abnormalities in children with and without autism spectrum disorder (ASD). The SSP is a shortened version of the Sensory Profile (SP; Dunn 1999), a 125-item survey that assesses sensory features according to the theoretical framework of Winnie Dunn (1997, 2001, 2007). The SSP questionnaire contains 38 items organized into 7 empirically derived subscales: tactile sensitivity (TAC; 7 items), taste/smell sensitivity (TSM; 4 items), movement sensitivity (MOV; 3 items), underresponsive/seeking sensation (USS; 7 items), auditory filtering (AFL; 6 items), low energy/weak (LEW; 6 items), and visual/auditory sensitivity (VAS; 5 items). All items are rated on a 1–5 Likert-type scale based on the frequency of the described behavior (1 = Always, 2 = Frequently, 3 = Occasionally, 4 = Seldom, 5 = Never). Scores are typically calculated by summing all items across a given subscale, and the SSP total score is often used as a measure of overall sensory symptomology. As lower item scores indicate more frequent atypical behaviors, lower SSP total and subscale scores are indicative of more pronounced sensory processing dysfunction. The SSP total score and the score on each subscale can be used to classify a child's level of sensory abnormality as "typical," "probable difference," or "definite difference" based on score percentiles from a large normative sample of children without disabilities 3–10 years of age ($N \approx 1200$).

In recent years, the second edition of the Sensory Profile (SP2; Dunn 2014) has been released, along with a shortened version similar to the SSP (SSP-2). The SSP-2 contains 34 items organized into subscales representing the four "sensory quadrants" of Dunn's theoretical model (sensory sensitivity, sensory avoiding, low registration, sensory seeking). A large number of items are shared between the SSP and SSP-2, but the latter measure has been modified to improve content coverage of specific sensory response patterns (such as hyporeactivity/low registration) that are poorly represented in the original SSP. The format of the SSP-2 is similar to that of the SSP, with behaviors being rated on a 1–5 Likert-type scale representing frequency ("almost never" to

"almost always"). However, unlike the previous version, *higher* scores on the SSP-2 represent increased frequency of the atypical behaviors. Scores on the SSP-2 and its subscales can also be compared to a large normative sample of children without disabilities aged 3–14 years ($N = 697$), allowing for a child's score to be characterized as abnormally high or low.

Historical Background

The Short Sensory Profile was developed as a short form of Dunn's Sensory Profile caregiver questionnaire, with the goal of maximally discriminating between typical children and those with clinically significant sensory processing dysfunction. The 38-items of the SSP were chosen based on psychometric analyses of SP questionnaires completed by the caregivers of 117 children aged 3–17 years: 21 with clinically diagnosed sensory modulation disorder (SMD); 24 with fragile X syndrome (FXS); 35 with other developmental disabilities, including but not limited to ASD; and 37 with typical development (TD). From the 125 original SP items, 27 were immediately eliminated based on item content outside the domain of sensory modulation issues. Sixty additional items were removed based on (a) poor discrimination between SMD and TD groups, (b) low item-total correlations with conceptually similar sections of the full-length SP, (c) low item loadings in a principal component analysis (PCA) using the large normative SP validation sample, and (d) increased subscale Cronbach's alpha upon removal of the item. The final 38 items were then subjected to another PCA in the large normative sample, from which the seven SSP subscales were derived.

As the SP and SSP were some of the first proxy-report measures of sensory processing available, they were quickly applied to the study of sensory features in ASD. In the first study of this sort, Kientz and Dunn (1997) compared SP item scores between 32 children with ASD and 64 TD controls, finding significant group differences in 84 of 99 items. The first study to employ

the SSP was that of Rogers and colleagues (2003), who found that scores on five of the SSP subscales (TAC, TSM, USS, AFL, and LEW) differentiated children with ASD or FXS from mental age-matched children with other developmental disabilities or TD. However, the measure remained fairly obscure in autism research until 2007, when the measure's creator published a large retrospective study comparing SSP item, subscale, and total scores between 281 children with ASD and 281 age-matched TD controls (Tomchek and Dunn 2007). In this seminal study, the ASD group exhibited a strikingly high incidence of sensory processing issues, with SSP total scores classifying 83.6% and 11.4% of ASD children as having a "definite difference" (83.6%) or "probable difference" (11.4%) in sensory processing, compared to 3.2% and 13.6% in the TD group. Substantial numbers of ASD children also scored within the "definite difference" range in each of the SSP subscales (23.1–86.1%). Mean differences between the groups were highly significant for all SSP subscales, with small to moderate effect sizes ($d = 0.219$ – 0.628) for five of the seven subscales (TAC, TSM, USS, AFL, and VAS). Smaller effects were found for group differences in the MOV subscale ($d = 0.039$), LEW subscale ($d = 0.109$), and SSP total score ($d = 0.115$). Lastly, 35 of the 38 items (all except "prefers long-sleeved clothing even when it is warm or short sleeves when it is cold," "dislikes activities where head is upside down," and "covers eyes or squints to protect eyes from light") showed significant between-group differences at the $p < 0.001$ level ($d = 0.243$ – 0.652). These figures form the basis for the oft-cited claim that greater than 90% of children with ASD exhibit sensory processing impairments.

After the publication of Tomchek and Dunn's study, the use of the SSP in autism research increased substantially. Based on a review of 93 studies assessing sensory processing in ASD, the SSP was the second most utilized sensory phenotyping measure (28.0% of studies) after the full-length SP (Burns et al. 2017). Additionally, the SSP has been the sole sensory measure employed in several large-scale autism phenotyping projects (Charman et al. 2017;

Lajonchere et al. 2012; Singer 2005). The SSP and its subscales are frequently used as dimensional measures of sensory features, serving to quantify the relationships between specific patterns of sensory reactivity and other clinical or neurophysiologic measures (e.g., Glod et al. 2015). A separate group of studies has investigated profiles of SSP subscale scores from children with ASD to define phenotypic subgroups using cluster analysis techniques (Hand et al. 2017, 2018; Lane et al. 2010, 2011, 2014; Simpson et al. 2019; Tomchek et al. 2018; Uljarević et al. 2016). The SSP total score is also frequently utilized in the development of newer sensory measures to establish convergent validity (Neil et al. 2017; Siper et al. 2017; Tavassoli et al. 2016). Although the SSP-2 has been available for a number of years, its use in autism research thus far has been very limited (Simpson et al. 2019). This phenomenon may be due to the increased numbers of sensory measures now available for use in research paradigms, the large amount of SSP data that has already been collected, the relative paucity of studies utilizing the SSP-2 in ASD, and the presence of psychometric validation studies of the SSP but not SSP-2 in the ASD population. Nevertheless, as more studies are published utilizing the SSP-2 in ASD, it is likely that this measure will come to replace the original SSP in research and clinical practice settings.

Psychometric Data

Despite the widespread use of the SSP in children with ASD, there have been relatively few studies assessing its psychometric properties in this population (McIntosh et al. 1999; Stevenson et al. 2019; Tomchek et al. 2014; Williams et al. 2018). As the SSP was developed using a large TD sample and a smaller mixed-diagnosis sample, the SSP test manual does not contain estimates of test reliability or validity that pertain directly to the ASD population. Nevertheless, the figures provided therein provide preliminary evidence of the measure's reliability and validity in a typical population. Internal consistency reliability was

estimated for the SSP subscales in the mixed-diagnosis sample of 117 children and found to be adequate in all cases ($\alpha = 0.82\text{--}0.89$). Construct validity was also assessed in a small study evaluating skin conductance responses to sensory stimuli in children with SMD ($n = 19$) and TD children ($n = 19$). Results showed that children with abnormal skin conductance responses (either greater than or less than the values of the TD group) scored lower on the SSP, indicating higher levels of sensory modulation difficulties than children with typical skin conductance (McIntosh et al. 1999). Known-groups validity was also established, both by the initial item-selection process (i.e., only choosing items that discriminated between children with SMD and TD; McIntosh et al. 1999) and by the ability of 92% of the SSP items to discriminate between ASD and TD groups with a small to moderate effect size (Tomchek and Dunn 2007).

To date, three studies have investigated the psychometric properties of the SSP in samples of children with ASD, focusing primarily on the questionnaire's latent structure. For much of the time that the SSP has been used in ASD, the seven subscales derived from the TD sample were assumed to represent the latent structure in this population. However, factor-analytic studies have generally disagreed with this assertion, suggesting that the latent structure of the questionnaire differs significantly in children with ASD (Tomchek et al. 2014; Williams et al. 2018). In the first study of this sort, Tomchek et al. (2014) carried out a PCA with varimax rotation on the 38 items of the SSP in a sample of 400 ASD children 3–6 years of age. The original 7-component solution of the SSP was not replicated in this sample, and the authors instead chose to report a 6-component structure based on interpretability. The TSM and LEW subscales from the original pattern were replicated, and the other four components were interpreted as (a) tactile and movement sensitivity, (b) auditory and visual sensitivity, (c) sensory seeking/distractibility, and (d) hypo-responsivity (Tomchek et al. 2014). More recently, Williams et al. (2018) utilized confirmatory factor analysis to test both the original 7-factor model and the revised 6-factor model of the SSP in a sample of

388 children with ASD aged 2–12 years. Based on widely accepted fit index guidelines (i.e., CFI/TLI > 0.95 , RMSEA < 0.06 , SRMR < 0.08 , and WRMR < 1.0 are indicative of good model fit; Hu and Bentler 1999; DiStefano et al. 2017), neither the 7-factor model (CFI = 0.922, TLI = 0.915, RMSEA = 0.071, SRMR = 0.086, WRMR = 1.603) nor the 6-factor model (CFI = 0.924, TLI = 0.918, RMSEA = 0.069, SRMR = 0.086, WRMR = 1.623) showed acceptable fit to the data. Furthermore, examination of the residual correlations showed multiple areas of local model misfit for both models, further suggesting they are inappropriate to describe the factor structure of the SSP in ASD children. Most recently, Stevenson et al. (2019) tested the original 7-factor SSP model in an independent ASD sample ($N = 361$, ages 1.88–21.89 years). Although these authors concluded that “fit indices indicated acceptable overall fit,” two of three reported model fit indices suggested that the model was not a good fit for the data (CFI = 0.865, RMSEA = 0.066, SRMR = 0.067). Together, these three studies indicate that the 7-factor model of the SSP derived in TD children is not valid in children with ASD and should be abandoned in favor of a structural model specific to this population.

After failing to confirm either of the proposed SSP models in an ASD sample, Williams and colleagues conducted an exploratory factor analysis, finding a 9-factor solution to best explain the covariance structure of the SSP. These factors were interpreted as (1) low energy/weakness, (2) taste/smell sensitivity, (3) hyperactivity/inattention, (4) tactile sensitivity, (5) movement sensitivity, (6) auditory distractibility, (7) hyporesponsiveness to speech, (8) visual sensitivity, and (9) noise distress. Seven of the 38 items (1, 2, 5, 15, 19, 21, 37) were found to be poor indicators of any factor and were thus dropped from the final model. Confirmatory factor analysis of the remaining 31 items indicated an acceptable fit of the 9 correlated factor model on all fit indices except the WRMR (CFI = 0.974, TLI = 0.969, RMSEA = 0.052, SRMR = 0.058, WRMR = 1.042). While this 9-factor model has yet to be replicated in independent samples, it

represents the most appropriate structural model proposed for the SSP to date. Moreover, the low energy/weak, taste/smell sensitivity, and movement sensitivity factors were unchanged from their original subscales, indicating that these three subscales in particular can be validly interpreted in children with ASD. The composition of each subscale is presented in Table 1.

Internal consistency reliability of the SSP and its subscales in children with ASD were reported by Williams et al. (2018). Reliability coefficients (coefficient ω) for the original seven SSP subscales were all acceptable, ranging from 0.76 (MOV) to 0.97 (LEW). However, the authors warned that these coefficients should only be interpreted for subscales that correspond to the underlying factor structure. Thus, the only interpretable ω coefficients are those for the TSM ($\omega = 0.94$), MOV ($\omega = 0.76$), and LEW ($\omega = 0.97$) subscales, which have equivalent factor structures in the ASD and TD populations. Based on their exploratory factor model, Williams et al. also estimated the internal consistency reliabilities (coefficient ω_s) for the nine empirically derived SSP subscales (Table 1). Internal consistency reliability for the various subscales varied substantially with the value for the “hypo-responsiveness to speech” indicating unacceptably low reliability ($\omega_s = 0.63$) but all other values surpassing the often-used acceptability

cutoff of 0.70 or greater (Nunnally and Bernstein 1994). Note that the values for TSM, MOV, and LEW differ somewhat from those mentioned previously, due to the prior values being calculated from unidimensional confirmatory factor models. Additionally, reliability of the summed SSP total score was found to be very high (coefficient $\omega_t = 0.96$), indicating that 96% of total score variance was attributable to the underlying latent factors. Internal consistency reliabilities of the SSP-2 quadrants in a sample of ASD children, as measured by Cronbach’s α , were reported to be adequate for three of the four scales (seeking $\alpha = 0.69$, avoiding $\alpha = 0.83$, sensitivity $\alpha = 0.75$, registration $\alpha = 0.75$; Simpson et al. 2019). No study to date has assessed other forms of reliability, such as test-retest and inter-rater reliability, for either the SSP or SSP-2.

Additionally, there has been little published work specifically assessing the validity of the SSP total and subscale scores in ASD. However, the aforementioned factor-analytic studies contribute somewhat to our understanding of the test’s structural validity in ASD. As four of the original seven SSP subscales (TAC, USS, AFL, and VAS) were not replicated in the best-fitting factor model (Williams et al. 2018), these scales do not seem to measure meaningful constructs in the ASD population and are thus not valid for use. Of the remaining scales, the TSM scale does seem to have some construct validity as a measure of food selectivity, supported by large correlations between TSM scores and other measures of food selectivity across samples of children with ASD (Williams et al. 2018). The construct validity of the two remaining subscales has not been assessed in this population, and it remains to be seen whether these sales are valid measures of their underlying constructs. The revised scales presented by Williams and colleagues also have not undergone any tests of construct validity. However, as several of these scales contain only two items, they likely do not represent all content areas of their underlying latent constructs and may have questionable content validity. Williams et al. (2018) also assessed the validity of the SSP total score as a measure of general sensory dysfunction, finding

Short Sensory Profile in Autism, Table 1 Empirically derived subscales of the Short Sensory Profile for children with ASD

Scale	SSP items	Reliability (ω_s)
Low energy/weakness	28–33	0.95
Taste/smell sensitivity	8–11	0.96
Hyperactivity/inattention	16–18, 20, 27	0.75
Tactile sensitivity	3, 4, 6, 7	0.78
Movement sensitivity	12–14	0.82
Auditory distractibility	22, 24, 25	0.81
Hypo-responsiveness to speech	23, 26	0.63
Visual sensitivity	36, 38	0.81
Noise distress	34, 35	0.79
Total score	1–38	$\omega_t = 0.96$

it to be a poor measure for this construct on multiple grounds. When modeled, a general sensory processing dysfunction factor explained a fairly low percentage of total score variance (coefficient $\omega_H = 0.68$). The scale's content validity was also called into question, as the SSP does not contain items assessing the full range of sub-constructs that contribute to general sensory processing dysfunction (Miller et al. 2007; Williams et al. 2018). Overall, it was recommended that the SSP total score not be utilized as a measure of general sensory processing dysfunction in children with ASD. To date, no study has assessed the validity of the SSP-2 or its subscales in children with ASD, although the form does seem to measure a wider range of sensory processing sub-constructs, thus improving its content validity.

Clinical Uses

The SSP has sometimes been utilized in clinical settings as part of a multidisciplinary assessment battery in young children with ASD and other developmental disabilities, helping to inform clinical recommendations for services such as physical or occupational therapy. The questionnaire was originally developed for clinical use by occupational therapists to screen for sensory processing dysfunction in children, and it is sometimes also used for this purpose in ASD. However, given the high likelihood of most children with ASD scoring in the abnormal range overall, some clinicians may prefer to use this test to examine which areas of sensory processing are contributing most to a child's difficulty. Some clinicians may also administer the SSP on repeated occasions to track a child's progress over time as he or she undergoes an intervention. However, no empirical data have been published on the suitability of the SSP or SSP-2 for informing clinical decision-making, guiding intervention choices, or reflecting the efficacy of ongoing interventions in children with ASD. Additional research is required to validate the SSP or the SSP-2 for clinical use in any of these domains.

Short-Term Memory

Laudan B. Jahromi and Crystal I. Bryce
School of Social and Family Dynamics, Arizona

Definition

Short-term memory refers to the immediate or temporary storage of information.

Historical Background

The limited data that can be stored in short-term memory will be lost if not repeated or rehearsed. An individual's ability to temporarily store information is considered to be a function of a variety of factors, including how the information was encoded, whether it could be rehearsed, and even the psychological state of the individual, such as his or her anxiety level (e.g., Darke 1988). Early work on memory suggested that short-term memory was a unified temporary storage system (Atkinson and Shiffrin 1968). According to Baddeley and Hitch (1974), short-term memory was later proposed to have several components, collectively referred to as working memory, responsible for simultaneously storing and operating on information for relatively short periods of time when an individual performs cognitive tasks. These three components of working memory were referred to as the central executive, the visuospatial sketchpad, and the phonological loop. The central executive component is conceptualized as a control system with a key role in identifying issues on which to focus attention, decision-making, and response selection (Boller 1996). The visuospatial sketchpad is considered responsible for storing visual and spatial information, while the phonological loop is responsible for storing sounds, and is thought to be important for language development (Baddeley 1992). More recently, Baddeley (2000) proposed a revision to the Baddeley and Hitch (1974) model by conceptualizing the central executive as a domain general

component that integrates or coordinates information from visuospatial and verbal information. Moreover, the new system proposed by Baddeley (2000) includes the notion of an "episodic buffer" which is thought to be a short-term storage system that is controlled by the central executive, integrates information, and plays a role in the exchange of information to and from episodic long-term memory.

Several theories exist concerning potential short-term memory deficits in autism (see Poirier and Martin 2008 for a review). Some have suggested that because short-term memory tasks require individuals to recall stimuli in their order of presentation, individuals with autism should show a deficit due to deficits in temporal processing (Boucher 2001). Others argue that difficulties with retrieval on short-term memory tasks, in particular, should be apparent in autism due to impairments in remembering contextual and personally experienced aspects of events (Bowler et al. 2004). Finally, there is some evidence of a group-by-difficulty interaction such that short-term memory impairments for higher-functioning individuals with autism may appear as task difficulty increases (Craig and Anderson 1999).

Current Knowledge

Although previous empirical findings suggested an intact short-term memory system in individuals with autism (e.g., Hermelin and O'Connor 1967), these studies may have had some methodological limitations, including a reliance on span-type tasks and use of a smaller than ideal number of trials (Poirier and Martin 2008). With respect to working memory, which is commonly considered a dimension of executive function, individuals with autism appear to show performance consistent with the types of deficits one might see in patients with frontal lobe damage (Hill 2004), leading many in the field to argue that autism is inherently a disorder of executive function. However, empirical findings indicating a working memory deficit specific to autism are somewhat mixed (see Poirier and Martin 2008 for a review of

current findings concerning working memory in autism). For example, in a study of verbal working memory, Bennetto et al. (1996) found individuals with autism (11–25 years of age) to be impaired in working memory in comparison to a comparison group of individuals with learning disorders. However, Russell et al.'s (1996) study of working memory found no significant difference between children with autism and a moderate-learning-difficulties comparison group, although both of these groups performed significantly worse than a normally developing comparison group. Some studies have even found no working memory deficits in their samples of individuals with autism (Guerts et al. 2004; Ozonoff and Strayer 2001). Differences in these studies may be a function of the difficulty of the task or the level of support provided to retrieve information (Poirier and Martin 2008). Interestingly, when studies have differentiated between tasks that allow the use of inner speech to regulate behavior (e.g., tasks like the Luria hand game) and those that require a verbal response and therefore do not allow for inner speech (e.g., the day/night task), group differences were not found in the latter tasks, supporting the contention by Russell and colleagues that individuals with autism have a particular impairment in their ability to use inner speech to rehearse the rules of working memory tasks (Russell 1997).

Finally, an alternative account of working memory deficits in autism has been put forth by Minshew and Goldstein (1998), who suggest that such deficits are a function of information processing difficulties that overwhelm working memory resources. Studies supporting this approach reveal that differences in working memory performance appear as the working memory load increases (Joseph et al. 2005).

Future Directions

Given the mixed findings to date on short-term memory and working memory deficits in autism, there is a clear need for future work in this area. According to Poirier and Martin (2008), future research should address whether verbal working

memory and spatial working memory are both equally affected in ASDs. There is also a need for more research on whether observed deficits are due to complex information processing issues and whether these vary according to task complexity and difficulty, or task support for retrieval. Future work should also explore the implications of deficits in short-term memory, for example, the extent to which verbal short-term memory difficulties may impact language development (Alloway et al. 2009).

Sibling emotion; Sibling relationship

Definition

Siblings of people with autism spectrum disorder (ASD) often play a large role in their brothers' or sisters' lives. Siblings can be teachers, models, and social partners, and, in later life, they can provide emotional, financial, and other functional support for the individual with ASD.

In order to maintain the health and well-being of both the sibling and the individual with ASD throughout these interactions across the lifespan, the siblings must have a positive relationship with each other. Although many individuals with ASD do have healthy relationships with their typically developing siblings, there are several aspects of ASD that may make it difficult for siblings to deal with. First, the social communication deficits of people with ASD may make it difficult for siblings to communicate with their brother or sister with ASD. Second, if the individual with ASD has a lot of behavior problems, such as aggression, then the sibling relationship may be not as close.

Overall, siblings of individuals with ASD tend to have less positive relationships with their brother or sister, even when compared to siblings of individuals with other intellectual and developmental disabilities (Shivers et al. 2019). Siblings of individuals with ASD who exhibit high levels

of behavior problems also tend to have lower levels of warmth and closeness in the sibling relationships (Hastings and Petalas 2014).

An important part of the sibling relationship is how the typically developing siblings feel about their brother or sister with ASD. Siblings of individuals with ASD have, on average, more negative beliefs about people with disabilities in general (Shivers et al. 2019). That is, siblings of people with ASD are more likely to believe that their brother or sister is a “problem” for the family or the classroom. Additionally, compared to siblings of individuals without disabilities, siblings of individuals with ASD report more overall negative feelings toward their brother or sister (Shivers and McGregor 2019). Importantly, however, siblings of individuals with ASD do not report lower levels of positive feelings toward their brother or sister (Shivers and McGregor 2019).

Although general research shows that siblings of individuals with ASD may struggle to develop close, positive relationships with their brother or sister and may feel, on average, more anxious and frustrated about their brother or sister, individual reports show a lot of variability in sibling experiences. Parents and siblings report nurturing relationship, with the typically developing sibling showing patience and pride when interacting with or teaching the individual with ASD (Dansby et al. 2018). Siblings also report strong feelings of family, indicating a sense of togetherness and protectiveness (Pavlopoulou and Dimitriou 2019). However, siblings also report many challenges. While survey research shows that behavior problems among the individual with ASD are related to less closeness in the sibling relationships (Hastings and Petalas 2014), siblings report more complexity – that is, seeing behavior problems in their brother or sister can make the sibling feel sad or helpless (Pavlopoulou and Dimitriou 2019). Finally, a common theme in sibling reports is the feeling that the world does not understand either the individual with ASD or the sibling experience (Dansby et al. 2018). Siblings believe that society does not

understand autism, and thus, life is harder for both them and their brother or sister.

Sibling feelings about their brother or sister with ASD are complex and wide-ranging. Although siblings of individuals with ASD, on average, have more negative feelings toward their brother or sister and less close sibling relationships, these feelings in total involve more than just anger and irritation. Siblings worry about their brother or sister, showing concern for both how the world will treat them now and in the future. They also report pride, warmth, and love. Overall, siblings of individuals with ASD acknowledge many challenges that can make it difficult to have a close relationship with their brother or sister, but many siblings still report numerous positive experiences with the individual with ASD.

Definition

Sibling supports are any services, interventions, or programs focused on typically developing siblings of individuals with intellectual or developmental disabilities, including autism spectrum disorders (ASD), with the goal of improving sibling well-being or increasing siblings' participation in the lives of their brothers or sisters with a disability. Sibling supports most often take the form of peer support but can also be informational sessions aimed at increasing knowledge about their brother or sister.

Historical Background

Sibling supports were initially developed in reaction to extant research and anecdotal reports suggesting that having a brother or sister with an intellectual or developmental disability, including ASD, can be difficult for some siblings (Lobato 1983; Meyer and Vadasy 1994). Although supports and services are often available to the individual with the disability himself or herself, supports are far less common for family members, including siblings.

The number of sibling support programs and interventions has increased somewhat over the past 20 years; Sibshops (Meyer and Vadasy 1994) is perhaps the first and best-known example of a sibling support. Many of the sibling support programs that have followed either incorporate aspects of the Sibshop model or build on it. It is

important to note that support interventions and programs for siblings have typically been geared toward siblings of individuals (mostly children) with any intellectual or developmental disability, including siblings of those with ASD. With the exception of one program, none of these supports specifically targets siblings of individuals with ASD.

Rationale or Underlying Theory

Sibling support programs and interventions share two main rationales. The rationale for programs that mainly focus on fostering sibling peer support – such as Sibshops (event-based program for siblings of children with disabilities: Meyer and Vadasy 1994), Sibkids (an internet listserv for siblings of children with disabilities developed as part of the Sibling Support Project, the umbrella organization that also includes Sibshops), and support group for siblings of children with ASD based at the Thistletown Regional Centre in Toronto, Ontario (Smith and Perry 2004) – is that being a sibling of an individual with intellectual and developmental disabilities can be a primarily positive experience, primarily negative experience, or a combination of the two. Furthermore, these siblings face unique challenges and experiences not shared by children who do not have a brother or sister with disabilities. Thus, developing peer supports with others who have a brother or sister with intellectual or developmental disabilities will allow siblings to discuss their experiences with others who understand, leading to wellness and well-being.

The rationale for sibling supports that are more informational in nature – such as the Sunsibs program based at Sunfield residential school in the United Kingdom (described in Conway and Meyer 2008), the Siblink program (Lobato and Kao 2002), the “Intervention for Siblings: Experience Enhancement” program (ISEE; Williams et al. 2003), and an unnamed program focused on siblings from socioeconomically disadvantaged families living in the inner city (Phillips 1999) – is that increasing siblings’

knowledge about their brother or sister's disability, behaviors, and needs will be beneficial to the nondisabled siblings. Specifically, increasing knowledge might lower the stress experienced by these siblings, help them to develop a closer relationship with their brother or sister with disabilities, and prepare them for the possibility of providing care for their brother or sister in adulthood.

Goals and Objectives

Existing sibling support programs have three general goals/objectives: increasing peer support, sharing of information, and increasing involvement of the sibling with the brother or sister with the disability. The Sibling Support Project, which includes both Sibshops and the Sibkids/Sibnet listservs, has the primary objective of *fostering peer support*. The Sibshop guidebook (Meyer and Vadasy 1994) lays out five specific goals related to this objective: (1) "Provide brothers and sisters of children with special needs an opportunity to meet other siblings in a relaxed, recreational setting"; (2) "Provide brothers and sisters with opportunities to discuss common joys and concerns with other siblings of children with special needs"; (3) "Provide siblings with an opportunity to learn how others handle situations commonly experienced by siblings of children with special needs"; (4) "Provide siblings with an opportunity to learn more about the implications of their sibling's special needs"; and (5) "Provide parents and other professionals with opportunities to learn more about the concerns and opportunities frequently experienced by brothers and sisters of people with special needs." As can be seen from these specific goals, sharing of information from one sibling to another (and not necessarily from teacher to sibling) is also an important aspect of Sibshops. Although not as well defined, the internet listserv arm of the Sibling Support Project (Sibkids for children and Sibnet for adults) has the objective of providing peer support and discussion in a secure environment.

Two of the existing sibling support programs have the primary objective of *increasing knowledge about the brother's or sister's disability*. The Thistlethorn program (Smith and Perry 2004) has perhaps the most delineated specific goals from this group of programs, including the following: (1) increasing knowledge and understanding of ASD and related developmental disorders, (2) providing the opportunity for siblings to discuss their feeling in an accepting environment, (3) helping siblings to share ways of coping with difficult situations unique to having a sibling with autism, (4) enhancing siblings' self-concepts, and (5) encouraging siblings to have fun in a supportive environment. As can be seen from these goals, sibling peer support is also an objective of the Thistlethorn program. The ISEE program (Williams et al. 2003) has the specific objectives of improving sibling knowledge, as well as improving siblings' perceptions of and affective reactions to their brother's or sister's illness or disability (this program also included siblings of children with chronic illness).

The support program geared toward socioeconomically disadvantaged children (Phillips 1999) and the SibLink program (Lobato and Kao 2002) both promote *providing information and enhancing peer social support* as equal objectives. Specifically, the program for disadvantaged families has the goal of alleviating the stress of having a sibling with an intellectual disability by providing information about developmental disabilities to facilitate understanding and by creating a context that provides social support from peers and adults. The SibLink program has the goals of improving sibling knowledge, sibling adjustment to living with a brother or sister with a chronic illness or developmental disability, and sibling connectedness to others who have a brother or sister with a chronic illness or developmental disability.

Finally, the Sunsibs program (as described in Conway and Meyer 2008) has the primary objective of *increasing involvement of the sibling in the lives of his/her brother or sister with ASD or other disabilities*. In order to increase sibling involvement, Sunsibs has the specific goals of providing

opportunities for siblings of children in the Sunfield program to meet other siblings and build relationships with them, of keeping siblings in touch with the Sunfield facility, and of helping siblings feel an integral part of their brother's or sister's lives while that brother or sister is participating in the Sunfield programs.

As can be seen from the above descriptions, sibling support programs differ in the emphasis placed on facilitating increased peer support, sharing of information, and increased involvement of the sibling with the brother or sister with the disability. Furthermore, many of the programs incorporate two or three of these themes into their overall goals or objectives.

Treatment Participants

The majority of sibling supports focus on school-aged children. Sibshops were originally developed for siblings aged 8–13 years but had been adapted to older or younger school-aged children (Conway and Meyer 2008; Meyer and Vadasy 1994). The Sibkid listserv is geared toward siblings under 18 years of age. The Thistle town program included siblings aged 6–16 years (Smith and Perry 2004), ISEE included siblings aged 7–15 years (Williams et al. 2003), and the program for disadvantaged children included siblings aged 9–12 years (Phillips 1999). Further, the SibLink program included siblings aged 8–13 years (Lobato and Kao 2002). Two of the programs are open to adult siblings. The Sunsibs program allows adult siblings to participate, as long as their brother or sister with the disability is between 6 and 19 years of age (Conway and Meyer 2008). The Sibnet listserv is open to siblings who are 18 years of age or older.

Nearly all of the existing sibling supports focus on siblings of individual with intellectual or developmental disabilities more generally, including those with ASD. The sole program that included only siblings of individuals with ASD is the Thistle town program. Two of the sibling supports – the ISEE and SibLink programs – included siblings of children with chronic illness

in addition to siblings of children with developmental disabilities.

Treatment Procedures

Sibling supports take the form of workshops/events, one-on-one supports, and secure internet listservs. Specific information about the procedures and content for each program can be found in the References and Readings. Workshops and events are the most prevalent type of procedure. Sibshops (Meyer and Vadasy 1994) consist of events that contain a mix of information, discussion, games, activities, and guests. The Thistle town program is an 8-week, age-specific support group that includes exercises, games, and activities promoting group cohesion, informational session on autism and related disorders, and discussions of feelings and attitudes associated with living with a person with a developmental disability (Smith and Perry 2004). Similarly, the SibLink program consists of six 90-min sessions conducted over 6–8 weeks, focused on improving sibling knowledge and family communication, managing feelings about having a brother or sister with a disability, and discussing how to balance siblings' own needs (Lobato and Kao 2002). The SibLink program also includes recreational activities at each session. The ISEE program contains structured teaching about the brother's or sister's disability or illness and psychosocial sessions over the course of a 5-day summer camp and two follow-up booster sessions (Williams et al. 2003). The program for socioeconomically disadvantaged children consists of an after-school program that lasts for 15 weeks and involves discussion about developmental disabilities, recreational activities, and homework assistance (Phillips 1999). The commonalities among most of these programs are the following: (1) having a specific starting and ending point with a limited number of sessions (except for Sibshops, which is ongoing) and (2) inclusion of social, informational, and recreational components.

The other procedures are less common. The Sunsibs program involves more direct support and training to the sibling, whereas the Sibkid

and Sibnet listservs involve siblings in posting and responding to messages on a secure website.

Efficacy Information

All of the sibling supports except for Sunsibs and the Sibkids/Sibnet listservs have some information about efficacy. However, it is difficult to draw conclusions about efficacy as the authors were only able to find one study that tests efficacy for most of the programs. Specific information about efficacy for each program is available in the References and Readings. Four of the five studies included standardized, validated measures as indicators of efficacy. Two programs – the ISEE program and the program for socioeconomically disadvantaged children – included before and after treatment measures and a control group that did not receive the treatment. For the ISEE program, researchers found improvements in knowledge and attitudes, social support, and self-esteem, and to some extent, behavior problems for siblings in the full-treatment condition (structured teaching and psychosocial sessions at summer camp) and improvements in attitude, self-esteem, and social support in the partial-treatment condition (summer camp only). Researchers concluded that there were dosage effects, with the full-treatment siblings showing the most improvement and partial-treatment siblings showing more improvement than controls (Williams et al. 2003). Researchers testing the program for socioeconomically disadvantaged children collected data on sibling depression, anxiety, perceived social support, and sibling relationship. They found improvement in each of these measures from before to after intervention, with no improvement in the control group (Phillips 1999).

Efficacy evaluation of two of the interventions – the Thistle town and SibLink programs – included standardized measures taken before and after intervention but no control group. Siblings who participated in the Thistle town program reported increased self-concept and greater knowledge about their brother's or sister's disability (ASD) at the conclusion of the program, but there were no significant differences in coping

(Smith and Perry 2004). After treatment, participants in the SibLink program reported more accurate knowledge of their brother's or sister's disability, greater connectedness with that sibling, and fewer behavior problems relative to pre-treatment (Lobato and Kao 2002).

Finally, efficacy of Sibshops was not evaluated by standardized measures, but instead by asking 30 sibling participants about their feelings regarding the program (Johnson and Sandall 2005). Evaluators found that over 90% of surveyed siblings reported positive effects of Sibshops on their feelings toward their brother or sister, over 60% stated that Sibshops taught them coping skills, and 94% said that they would recommend Sibshops to others. In a study of 16 Sibshops participants, D'Arcy, Flynn, McCarthy, O'Connor, and Tierney (2005) found that 14 children reported that they liked the program, with 11 rating Sibshops as "excellent" or "very good," though the participants showed no significant improvements in self-esteem after attending Sibshops.

In sum, there is some evidence to suggest that sibling supports are effective in improving sibling knowledge about their brother or sister with disabilities and sibling psychosocial and behavioral outcomes. Further study is needed to determine whether benefits of each of these sibling supports are also found in other samples.

Outcome Measurement

A number of standardized measures used to determine efficacy were included in the studies. There were no common efficacy measures across studies. In other words, each instrument was used as an indicator of efficacy in only one of the interventions/support programs. Self-esteem and self-concept were measured using the Piers-Harris Children's Self-Concept Scale (Piers and Harris 1969), the Self-Perception Profile for Children (Harter 1985), and the Self-Esteem Questionnaire (DuBois et al. 1996). Sibling psychological well-being was measured using the Child Depression Inventory (Kovacs 1992) and the Children's Manifest Anxiety Scale-Revised (Reynolds and Richmond 1985). Sibling behavior problems

were measured using the Eyberg Child Behavior Inventory (Eyberg and Robinson 1983) and the Child Behavior Checklist (Achenbach and Edelbrock 1983). Sibling social support was measured with the Social Support Scale for Children (Harter 1985) and the Perceived Social Support Scale-Revised (Procidino and Heller 1983). A number of different measures of sibling knowledge of, attitudes about, and relationship toward their brother or sister with the disability were used to determine efficacy, many of which appear to be developed for that specific research project. Exceptions include the Autism Knowledge Measure for Young Children (Perry 1989), the Sibling Relationships Questionnaire (Furman and Buhrmester 1985), and the Sibling Perception Questionnaire (Hodapp et al. 1997; Sahler and Carpenter 1989).

Qualifications of Treatment Providers

Just over one-half of the sibling supports have no specified qualifications for treatment providers except for training in that specific support program. The exceptions are the ISEE program, which uses pediatric nurse clinicians to deliver treatment, and the program for socioeconomically disadvantaged children, which require team leaders to have a minimum of 3 years of experience working with families of children with developmental disabilities and at least a high school education. The SibLink program was delivered by two doctoral-level trainees in psychology or psychiatry for each sibling group.

Definition

Sign language is a system of communicating visually and spatially through signs created with the hands. The term “sign language” does not specify a particular sign system such as American Sign Language (ASL) or manual codes of English such as Seeing Essential English (SEE I), Signing Exact English (SEE II), Linguistics of Verbal English (LOVE), and Conceptually Accurate Signed English (CASE).

However, the word “language” denotes a rule-governed system of communication and not a code for a language. ASL is the natural language of the deaf community in the United States and much of Canada (Neidel et al. 2000). ASL is a distinct language from spoken English, while manual codes of English are based on spoken English and are an attempt to represent English on the hands. Typically, when signing is employed in the language intervention for children with autism, the type of signing systems that are used are manual codes of English rather than ASL. The main reason for this may be the hope that using sign language will lead to verbal communication, an outcome which has been supported by research (Schlosser and Wendt 2008).

Simon Baron-Cohen

Marc Woodbury-Smith
Department of Psychiatry and Behavioural
Neuroscience, McMaster University, Hamilton,
ON, Canada
Institute of Neuroscience, Newcastle University,
Newcastle upon Tyne, UK

Name and Degrees

Simon Baron-Cohen, PhD, New College Oxford
BA and an MPhil in Clinical Psychology at the
Institute of Psychiatry, Kin's College London. He
received his PhD in Psychology from University
College in London under the supervision of Prof.
Uta Firth.

Major Appointments (Institution, Location, Dates)

Simon Baron-Cohen is Professor of Developmental
Psychopathology, University of Cambridge and Fel-
low at Trinity College, Cambridge. He is Director,
Autism Research Centre (ARC) in Cambridge. He
has a degree in Human Sciences from New College,
Oxford, a PhD in Psychology from University Col-
lege London (UCL), and an MPhil in Clinical

Psychology at the Institute of Psychiatry, London,
and has held lectureships in these departments.
Baron-Cohen is a Fellow of the British Academy.

Major Honors and Awards

Baron-Cohen has received many awards. These
include awards from the British Psychological
Society (BPS) (Spearman Medal and May
Davison Award), the American Psychological
Association (McCandless Award), and the Phila-
delphia Autism Association/Princeton University
(Autism Award). He has also been awarded the
Presidents' Award from the BPS and the Joseph
Lister Lecturer from the British Association for
the Advancement of Science (BA). He has a Life-
time Achievement Award from MENSA and the
Kanner-Asperger Medal from the German Society
for Research into Autism.

Baron-Cohen is a Fellow of the British and
American Psychological Associations and of the
British Academy. He is Vice-President of the
National Autistic Society, Autism Anglia, and
was President, Psychology Section of the British
Association and Vice-President, International
Society for Autism Research (INSAR). He was
Chair of the NICE Guideline Development Group
for Autism (Adults) and is Scientific Advisor or
Patron to 6 autism charities and a member of the
Department of Health Program Board, Autism
Strategy. He is Chair of the Psychology
Section of the British Academy. He is co-editor
in chief of the journal *Molecular Autism* and is on
the Editorial Board of many journals, including
the *Lancet Psychiatry*. He is President-Elect of
INSAR and a National Institute of Health
Research (NIHR) Senior Investigator.

Landmark Clinical, Scientific, and Professional Contributions

Among his many publications, Baron-Cohen is
author of books such as *Mindblindness*, *The
Essential Difference*, *Prenatal Testosterone in
Mind*, and *Zero Degrees of Empathy*. He has
edited scholarly anthologies including *Under-
standing Other Minds*, *Synaesthesia*, and *The*

Maladapted Mind. He has written books for parents and teachers including *Autism and Asperger Syndrome: The Facts*, and *Teaching Children with Autism to Mind-read*. He has celebrated autism in *An Exact Mind*. He is author of the DVDs *Mind Reading* and *The Transporters*, to help children with autism learn emotion recognition, both nominated for BAFTA awards.

Short Biography

Baron-Cohen has a long history in the study of Autism Spectrum Conditions (autism) and is the author of more than 450 scientific articles. In 1985 he formulated and went on to test the “mindblindness” theory of autism in one of his many landmark papers. Baron-Cohen devised a puppet paradigm, the Sally-Anne test, to show that children with autism were impaired in the ability to attribute a false belief to others. This began a rich body of research, which demonstrated that children and adults with autism had fundamental difficulties with tasks that required a “theory of mind.” As part of this, he developed a number of measures of theory of mind as well as other dimensions of cognition, such as systemizing and empathizing, which have been used extensively in both research and clinical settings. In 1997, he formulated and went on to test the “fetal sex steroid” theory of autism. Among his other contributions to the field of autism, include studies of prevalence and screening, autism genetics, autism neuroimaging, autism and technical ability, typical cognitive sex differences, and synesthesia. As part of his research, Baron-Cohen has supervised more than 30 PhD theses.

Baron-Cohen also has a strong history in the clinical care of individuals with autism, with a particular focus on adults with Asperger Syndrome. In 1999 he created the first UK clinic for adults with suspected Asperger Syndrome, called the CLASS clinic (Cambridge Lifespan Asperger Syndrome Service), at a time when the National Health Service (NHS, UK) did not see the clinical need for this. This has helped over 1,000 patients to have their disability recognized, the “lost generation” of adults who had missed out on diagnosis in childhood, and has been used to create a

model for similar clinical services all over the UK. As part of this clinical work, he developed both a screening questionnaire (the Autism Spectrum Quotient, or AQ) and diagnostic instrument (the Adult Asperger Assessment, AAA). In 2016 he appeared in the BBC2 documentary *Employable Me*, revealing the remarkable strengths in people with autism and discussing how to promote inclusion. He has also written of the need to conceptualize autism as a difference rather than disability, a conceptual shift strongly supported by individuals with autism and their advocates, and he coined the term autism spectrum conditions, instead of autism spectrum disorders, to reflect this paradigm shift.

CPEP-3: Chinese Psychoeducational Profile Third Edition

Description

The Simplified Chinese Psychoeducational Profile Third Edition (sCPEP-3) is a comprehensive

measurement tool developed for the assessment of Chinese children with autism spectrum disorder (ASD) in mainland China. The instrument can be used to assess children aged between 6 months and 7 years old. The sCPEP-3 has two major components: the Performance Test and the Caregiver Report. The 172-item Performance Test consists of ten subtests administered by professionals based on direct observation and testing. The first six subtests focus on a child's developmental abilities, among which three subtests measure communication ability, Cognitive Verbal/Preverbal (34 items), Expressive Language (25 items), and Receptive Language (19 items), and another three subtests measure motor ability: Fine Motor (20 items), Gross Motor (15 items), and Visual-Motor imitation (10 items). The remaining four subtests of the Performance Test measure maladaptive behaviors including Affective Expression (11 items), Social Reciprocity (12 items), characteristics motor behaviors (15 items), and characteristics verbal behaviors (11 items). The 38-item Caregiver Report is completed by parents or major caregivers (e.g., parents, teacher, or guardian) based on their daily observations of the child in natural settings. The Caregiver Report contains three subtests, which measure Problem Behavior (10 items), Personal Self-Care (13 items), and Adaptive Behaviors (15 items), respectively. The scoring of items has been quantified with "Fail" = 0, "Emerging" = 1, and "Pass" = 2.

The sCPEP-3 covers both key developmental areas and maladaptive behaviors related to the diagnosis of ASD and thus can be used to measure the developmental strengths, weaknesses, and learning style of a child with ASD. The results constitute a comprehensive evaluation profile of the child, which helps therapists and professionals set up individualized treatment strategies and educational programs according to the child's unique characteristics (Schopler et al. 2005). In particular, the Caregiver Report in the sCPEP-3 gathers information about a child's self-care skills, behavioral problems, and adaptive behaviors based on the caregiver's daily observation of the child's performance. Several advantages of the Caregiver Report need to be noted. First, caregivers' evaluation of the child concerned is based on real-life experience over

a long period of time, which can well supplement the results of the assessment conducted by professionals within a short period of time. Second, children's behavioral problems, personal self-care skills, and adaptive behaviors reported by caregivers serve as important information for researchers to gain a holistic understanding of children with ASD. Third, the gathered information about the child's daily routine is important for the development of individualized intervention plan (Shek and Yu 2015). The Caregiver Report is usually conducted before the administration of the assessment by therapists.

Historical Background

To design and implement effective and early treatment strategies for children with ASD, it is necessary to have a comprehensive and accurate evaluation of the child's developmental strengths and deficits. An ideal assessment should have the following critical components. First, the assessment should be addressing all of the major areas of the child's development. Second, the assessment should be age-normed for use in early childhood to indicate the progression of skill development. Third, the items should be directly linked to the program targets. Fourth, the assessment should yield results to guide the development of a structured treatment program. Last but not least, the assessment should be able to track and monitor the child's development in key areas over time (Gould et al. 2011).

To this end, Schopler and Reichler (1979) first developed the Psychoeducational Profile (PEP) to assess children with ASD from preschool age to elementary age (i.e., 2–7 years old). The PEP was also intended to be used as a tool for planning and developing individualized educational programs within the TEACCH program. This instrument incorporates children's behavioral and developmental information, emphasizes the connection between the developmental delays of children with ASD and their atypical features, and provides a useful framework for researchers and practitioners to assess the development of children with ASD (Coonrod and Marcus 2013). In 1990, PEP was revised into the PEP-Revised (PEP-R)

(Schopler et al. 1990). Compared with the PEP, the PEP-R added items related to the developmental features for underage children. The language functioning sections and items related to problem behaviors of children with ASD were also expanded and updated. Another main characteristic of PEP-R is its easy and flexible administration, which further facilitates practitioners to use the tool in developing personalized treatment strategies for children. The PEP-R has been translated into several languages and used in different cultures, such as Chinese (Ka-ting Lam and Rao 1993; Shek et al. 2005), Dutch (Steerneman et al. 1997), and Brazilian (De Leon et al. 2004). In 2005, the PEP-R was revised into the PEP-third (PEP-3), which further updated the behavioral items corresponding to the latest research findings. The PEP-3 utilized more simple and concrete materials and instructions than the previous version, which makes the instrument more suitable for children with ASD aged between 6 months to 7 years old. The newly added Caregiver Report, a questionnaire completed by caregiver, provides a more comprehensive picture for the special learning strengths and weakness of children with ASD and helps practitioners, professionals, and researchers to formulate suitable and tailored intervention strategies and plan (Schopler et al. 2005).

The PEP-3 was first translated into Mandarin Chinese in Taiwan based on the guidelines for cross-cultural adaptation of instruments (Wild et al. 2005). Researchers made some modifications of the items such as reading English letters, words, sentences, and stories based on the Chinese culture in Taiwan context (Fu et al. 2010). The psychometric properties of this version of the PEP-3 were examined based on relatively small samples of children in Taiwan (Chen et al. 2011; Fu et al. 2010). In 2013, Heep Hong Society, the biggest organization in Hong Kong that provides professional training and education to children with developmental and learning problems and their families, invited a group of experts consisting of psychologists, occupational therapists, special educators, and special child-care workers to translate the PEP-3 into Traditional Chinese and conducted a validation study to examine the psychometric properties of the

instrument (Shek and Yu 2014, 2015). Since then, the CPEP-3 has been widely adopted by helping professionals and researchers working with children with ASD in Hong Kong. So far, the CPEP-3 has been used as an important educational assessment in more than 50 child centers to guide practitioners' development and evaluation of individualized educational plans for children with ASD.

More recently, researchers further converted the CPEP-3 into a Simplified Chinese version (sCPEP-3) for its use in mainland China (Yu et al. 2019). Although Hong Kong and mainland China are all Chinese-speaking regions, they still have significant language, culture, and lived experiences differences. In particular, Mandarin and Simplified Chinese characters are widely used in most areas of mainland China, and Cantonese and Traditional Chinese characters are employed in Hong Kong. Not only the pronunciations of Mandarin and Cantonese but also the vocabulary and grammar of written Chinese used in these two regions are different. Considering the language and cultural differences, bilingual researchers first reviewed the converted sCPEP-3 and made minor modifications to the wordings of a few items. A few more culturally suitable objects were further adopted to replace the original ones. Finally, a bilingual expert team examined the sCPEP-3 and compared with the original CPEP-3 to ensure that the two versions are conceptually equivalent. To provide empirical evidence for the application of the sCPEP-3 in the context of mainland China, a validation study that examined the psychometric properties of the sCPEP-3 was conducted (Yu et al. 2019).

Psychometric Data

Given the advantages of CPEP-3, scholars have conducted validation studies in different Chinese contexts. In Taiwan, evidence on the reliability and validity of both the Performance Test and the Caregiver Report has been reported. Based on samples of children with ASD, researchers

reported high internal consistency (Cronbach's alpha coefficients ranged between 0.92 and 0.98), good to excellent inter-rater reliability, and test-retest reliability (Fu et al. 2010, 2012) of the Chinese Psychoeducational Profile Third Edition (CPEP-3).

In Hong Kong, several studies were carried out and published, which provided comprehensive psychometric data for the traditional Chinese version of the CPEP-3 (Shek and Yu 2014, 2015, 2018). Specifically, with a normative sample of 455 children with ASD and a comparison group of 281 children with typical development, researchers examined the construct validity of the CPEP-3. It was found that older children scored higher than younger children for both groups on different subsets of CPEP-3, while no gender difference was identified within the group with ASD. The results of the confirmatory factor analysis supported the three-factor theoretical model of the Performance Test. Shek and Yu (2018) further reported the test-retest reliability, inter-rater reliability, and criterion-related validity of CPEP-3 Performance Test. The Cronbach's alpha coefficients ranged from 0.89 to 0.97, the test-retest correlation coefficients were all above 0.82, and the inter-rater reliability ranged between 0.34 and 0.87. It was also found that the CPEP-3 Performance Test subtests were positively correlated with the Merrill-Palmer Revised Scales of Development (MPR) while negatively correlated with subscale scores of the Childhood Autism Rating Scale (CARS). These results suggest good criterion-prediction validity of the CPEP-3 Performance Test. With regard to the Caregiver Report, Cronbach's alpha coefficients ranged from 0.65 to 0.89, and the test-retest reliability was between 0.82 and 0.97 (Shek and Yu 2015). For validity, CPEP-3 Caregiver Report subscale scores were positively correlated with the Hong Kong Based Adaptive Behavior Scale (HABS), which measures similar social-cognitive and behavioral functioning constructs (Shek and Yu 2015). The findings suggest that CPEP-3 is a psychometrically sound instrument for the assessment of children with ASD in Hong Kong.

In 2018, a large-scale validation study on the sCPEP-3 was conducted in a representative sample of children in mainland China (Yu et al. 2019). A total of 554 Chinese children with ASD and 311 typically developing Chinese children participated in this study. The results showed that Cronbach's alpha coefficients ranged from 0.77 to 0.96 for the Performance Test subscales and from 0.80 to 0.86 for the Caregiver Report subtests. Mean inter-item correlation coefficients equaled to or exceeded 0.29 for all subscales, suggesting good internal consistency of the sCPEP-3. However, it was noted by the researchers that Cronbach's alpha coefficients for three subtests (Cognitive Verbal/Preverbal, Expressive Language, and Receptive Language) are 0.95 or higher, indicating that some items in these subscales may be redundant. All test-retest correlation coefficients were between 0.73 and 0.98, indicating good time sampling reliability of the instrument. The mean and median polychoric correlation coefficients for all subtests of the Performance Test ranged from 0.64 to 0.93, which provides support for the inter-rater reliability.

Convergent validity, construct validity, and factorial validity of the sCPEP-3 were examined in the study. First, correlation coefficients between children's scores on the sCPEP-3 subtests and three other questionnaires, Gesell Developmental Observation-Revised (GDO-R), Vineland Adaptive Behavior Scale (VABS), and Childhood Autism Rating Scale (CARS), were calculated. The findings support good convergent validity of the sCPEP-3. Second, no significant gender difference within the ASD group was found in the participants' scores of sCPEP-3, while children in the control group scored significantly higher than the children with ASD on all subtests, which provided solid evidence for the construct validity of the sCPEP-3. Third, a confirmatory factor analysis (CFA) was carried out to test the factorial validity of the sCPEP-3. Model fitting results support the three-dimensional theoretical model of the Performance subtest: communication, motor, and maladaptive behaviors. Based on these findings, it is concluded that the sCPEP-3 is a

psychometrically sound measure for researchers, practitioners, and professionals to assess and monitor the development of children with ASD in mainland China.

Clinical Uses

The sCPEP-3 is a promising tool that can be used by professionals to chart the development of Chinese children with ASD aged between 6 months and 7 years old in a comprehensive manner. The satisfactory psychometric properties of the sCPEP-3 suggest that this instrument can offer reliable and valid evaluative information for researchers and practitioners working with children with ASD in mainland China.

Several practical implications are worth noting. First, a comprehensive evaluation of children with ASD should base on the standardized observation scores from professionals, as well as the information provided by children's caregiver, such as parents, guardian, or teacher (Huerta and Lord 2012). The sCPEP-3, which contains a formal Performance Test and a Caregiver Report, enables the researchers and clinicians to integrate information from different sources; to obtain detailed data and an overall pattern of children's developmental strength, weakness, learning styles, maladaptive behaviors, and interests; and to set up personalized educational plan and educational strategies (Yu et al. 2019). Second, Chinese clinicians can use the sCPEP-3 in combination with other diagnostic instruments to improve the diagnostic accuracy of ASD and reduce the rate of unrecognized cases in mainland China. Although several ASD screening tools and diagnostic instruments have been utilized and validated for Mandarin-speaking children (Li et al. 2005; Yin et al. 2011; Zhou et al. 2017), validation studies are limited in the context of mainland China. The use of the validated sCPEP-3 can facilitate the development of structured treatment programs and promote the provision of individualized educational programs for Chinese children with ASD (Yu et al. 2019). Finally, the sCPEP-3 can serve as a credible and valid outcome measure

to evaluate the treatment effects of ASD program in China.

Simpson-Angus Scale for Extrapyramidal Symptoms

Lawrence David Scahill
Nursing and Child Psychiatry, Yale Child Study Center, Yale University School of Nursing, New Haven, CT, USA
Marcus Autism Center, Children's Healthcare of Atlanta, Atlanta, GA, USA
Department of Pediatrics, Emory University, Atlanta, GA, USA

Definition

The Simpson-Angus Rating Scale is a 10-item scale used to rate adverse neurological effects of antipsychotic medications more broadly. It involves direct observation and a brief neurological examination.

For example, the rating requires the clinician to observe the patient's gait and check for tremor, excessive salivation, as well as rigidity in the arms, shoulder, and neck.

Each item is rated from 0 to 4 and a total score can be obtained.

Definition

Sinequan (doxepin) is a tricyclic antidepressant medication that has largely fallen out of use as an antidepressant. It is approved for the treatment of adults with insomnia – especially midsleep awakening. It is associated with multiple adverse effects including poor coordination, confusion, and increased heart rate and also has a potential for cardiac arrhythmia. Other adverse effects include dry mouth, urinary retention, and constipation. There are no studies of the use of doxepin in children or adults with autism spectrum disorders.

Singapore is a young island city-state in South-east Asia with a diverse population of approximately 5.7 million (<https://www.singstat.gov.sg/modules/infographics/population>). Ethnic Chinese constitute approximately 76% of the residents, followed by ethnic Malays (13.6%), Indians (9.4%), and others (3.4%). Its relatively brief history as an independent state has been characterized by considerable economical and capital growth, four official languages (English, Mandarin, Malay, and Tamil; English is the official language of business, administration, and school instruction), an internationally strong and competitive educational system, as well as governmental and community visions of Singapore as an inclusive society (Lee 2004). It is within this context that this paper seeks to present and summarize the history and current development of services, education, and other

initiatives for individuals with autism spectrum disorder (ASD) and their families.

Legal Issues/Mandates for Service

Singapore signed the UN Convention on the Rights of Persons with Disabilities in November 2012 and ratified it in August 2013. Service development and provisions for individuals with disabilities in Singapore have been guided by national-level committees and advisory groups. The Enabling Masterplans (EMs) for the disability sector (EM 2007–2011, EM 2012–2016, and EM 2017–2021) are comprehensive disability-specific policy documents designed to chart the development of programs and services for people with disabilities in the public sector and aimed to enhance the integration of persons with disabilities in Singapore and maximize their potential for independent living. The EMs have specifically included ASD under developmental disorders in their definition of disability. ASD is also stated as one of the seven disability types in the Singapore government's classification of disability.

The EMs identified national priorities and guided the development of services to address these priorities. Of relevance to individuals with ASD are the following recommendations of the first Enabling Masterplan: the development and maintenance of quality programs and staff, the empowerment of family caregivers through education and training, transition planning, and the integration of students with disabilities in the education system that may bridge the gap between special and mainstream curriculum. The second Enabling Masterplan (2012–2016) prioritized the early identification of disabilities in community settings, the introduction of an additional national child screening appointment with the pediatrician at 24–30 months, the development and evaluation of inclusion strategies within preschool settings, the improved coordination of services across the life-span, and the development of a national database of individuals with disabilities (Enabling Masterplan 2012–2016 Steering Committee 2012; see also Poon and Lim 2012). The most recent 2017–2021 Enabling Masterplan

acknowledges the increase in the number of individuals receiving a diagnosis of ASD and the consequential need to provide more supports and services. It also prioritizes the development of services for a more inclusive society with lifelong educational and employment opportunities for all persons with disabilities and increasing supports for their caregivers and for people with autism and other disabilities as they grow older.

While the EMs provide guidance for the general disability sector, the needs of different disability groups are not homogenous. As such, the Autism Resource Centre (Singapore), with support from the Autism Network Singapore (ANS), embarked on a project to develop an Autism Enabling Masterplan (AEM) in 2018. The AEM aims to identify needs and gaps that are specific to the autism community, prioritizing and proposing solutions thereof. The goal is to provide a directional roadmap to guide the work in Singapore with a focus on empowering and enabling persons on the autism spectrum to realize their potential and live a good quality life. High-priority areas include employment, residential living options, and future care planning. The AEM is targeted to be published by end 2020.

Historical Background

There are currently no formal published studies on the prevalence of disability in Singapore. However, it has been estimated that approximately 3.2% of young children (0–6 years), 2.5% of school-aged children (7–18 years), and 2.5% of adults have some form of disability in the city-state (Enabling Masterplan 2012–2016 Steering Committee 2012). Of the preschool children referred to the National Child Development Programme (which serves young children presenting with developmental concerns), about a quarter (20–25%) present with features of ASD and a third (30–35%) with speech and language delays and associated disorders (Ho 2018). With increasing numbers of children with special educational needs being identified within the national educational system, the incidence of older children and adults with disabilities is likely to increase.

The Child Psychiatric Clinic (now known as the Child Guidance Clinic) at the Woodbridge Hospital (now known as the Woodbridge Hospital/Institute of Mental Health (IMH)) first identified and clinically diagnosed cases of autism (then termed infantile psychosis) in the 1970s. The first ASD-specific special education program was established in 1989 at Margaret Drive Special School, subsequently run by Rainbow Centre Singapore, serving both preschool and school-aged children with ASD (Poon et al. 2016). In 2004, Pathlight School was established as an ASD-specific school for young people on the spectrum who are able to access the mainstream curriculum with appropriate specialist teaching and in a ASD-specific learning environment (see section on “Educational Provisions for School Going Children ” below for more details).

Overview of Current Services, Centers, and Interventions

Diagnostic and Clinical Services

Around 1989, Dr. Vera Bernard-Opitz, a Senior Lecturer, joined the Department of Psychology at the National University of Singapore and volunteered at Margaret Drive Special School (Bernard-Opitz et al. 2001a). Shortly after, the Developmental Assessment Clinic was established in 1991 at the Singapore General Hospital (Ho 2007). This tertiary-level diagnostic facility for preschool children subsequently led to the development of a nationwide Child Development Programme funded by the Ministry of Health in 2002 in collaboration with two of the leading public hospitals in Singapore (National University Hospital (NUH) and KK Women and Children's Hospital (KKH)), which currently diagnoses and manages the majority of children with disabilities (including ASD) under the age of 7 years in Singapore. Through this program, approximately 1000 new cases of ASD in preschool children are diagnosed yearly (Ho 2018). More than half of Singaporean parents are concerned about their child's early development by the age of 2 years. The average age of ASD diagnosis in Singapore is at 3 years of age, which is at least as early as, and possibly earlier

than, other developed countries (Moh and Magiati 2012; Bernard-Opitz et al. 2001a). Since 1995, the Ministry of Education (MOE) has employed psychologists to provide psychological assessments and advice for students with special educational needs in mainstream primary and secondary schools. The number of students with special needs seen by the MOE psychologists, including those suspected to have ASD, has increased in recent years. As from 2007, REACH teams (Response, Early Intervention and Assessment in Community Mental Health), a community-based multidisciplinary mental healthcare service, have been working collaboratively with school counselors employed in mainstream schools to identify and support students with emotional, social, and behavioral issues, including those with ASD.

The specialist outpatient Neurobehavioral Clinic (Autism Services) was established in 2006 and has been providing diagnostic assessment for 6–19-year-old children and adolescents with suspected ASD and intervention services for those children and adolescents with ASD who present with mental health or behavioral comorbidities. This service is available within the Child Guidance Clinic, at the country’s largest mental health organization, the Institute of Mental Health (IMH). Visits to the Child Psychiatric (now Child Guidance) Clinic for a query of ASD in 7–18-year-old children and young people have increased substantially in recent years (see Fig. 1).

There were, until a few years ago, no specialist clinical services for the assessment, diagnosis, and support for adults with ASD. Since 2011, a

specialist multidisciplinary outpatient neurodevelopmental clinic for adults with intellectual disabilities or ASD and mental health or behavioral challenges (the Adult Neurodevelopmental Disorder Service) has been setup within IMH to support those individuals and their families and provide comprehensive assessment and intervention services. Although a minority of individuals are assessed and diagnosed in private settings, or in non-governmental voluntary welfare organizations (VWOs), the majority of children and young people with ASD are diagnosed at the earlier mentioned public organizations, where multidisciplinary teams (including pediatricians or child psychiatrists, nurses, psychologists, and other allied healthcare professionals) carry out comprehensive interdisciplinary developmental assessments. The Academy of Medicine Singapore-Ministry of Health Singapore Clinical Guidelines for Preschool Children with ASD (2010) recommends that assessment of suspected ASD be carried out by multidisciplinary teams through direct observation of the child; administration of ASD-specific instruments, such as the Autism Diagnostic Observation Schedule (ADOS) and the Autism Diagnostic Interview-Revised (ADI-R); and gathering of ASD-specific developmental information. Recommendations are then made for support, intervention, and management in the community.

Early Intervention

The Academy of Medicine Singapore-Ministry of Health Singapore Clinical Guidelines for Preschool Children with ASD (2010) recommends

Singapore and Autism Spectrum Disorder,
Fig. 1 Number of first visits to the Child Psychiatric/Child Guidance Clinic relating to possible autism/ASD

that all preschool children with ASD be referred at the earliest instance to an early intervention program that provides an individualized intervention plan with comprehensive and targeted interventions using visual strategies and emphasizes the use of augmentative communication systems and direct teaching of social skills.

Early intervention programs in Singapore are supported by the Early Childhood Development Agency (ECDA) from 1 April 2020. This signifies recognition that early intervention (EI) is an integral part of early childhood provision in Singapore. The early intervention provisions consist of a continuum of program types. The Early Intervention Programme for Infant and Children (EIPIC) supports children with moderate to severe developmental needs. There are approximately 3000 children including those with autism who are supported in 21 such centers. Some of these centers serve children with different developmental needs, while others provide specialized programs for children on the autism spectrum. At the other end of the spectrum, the Development Support-Learning Support (DS-LS) programs support children with mild developmental needs within their preschools. Therapists may work with the children and preschool teacher to enhance social communication and interactions, as well as attention and behavioral issues of students in the classroom.

To better support children with developmental needs and their families, EI services have been made more customized and affordable since July 2019. Two new programs have been introduced, namely, (a) EIPIC Under-2s and (b) Development Support (DS)-Plus. The EIPIC Under-2s program provides training to the parent/caregiver to carry out intervention strategies in the child's daily routines within their home setting even if the child does not have a formal diagnosis of ASD. This aims to help parents create learning opportunities throughout the child's daily life.

Development Support Plus (DS-Plus) on the other hand supports children with mild to moderate developmental needs within their preschools, rather than at a separate EI center. EI centers which have launched the enhanced EI programs will identify children for suitable EI programs that

are tailored to their developmental needs, through the use of an Early Intervention Benchmarking Framework. Parents will be kept up-to-date on their child's progress in EI and the child's suitability for a change in the level of intensity of EI, through the child's 6-monthly progress reviews.

Educational Provisions for School Going Children

Formal education in Singapore begins the calendar year as a child turns 7. Children with ASD can enroll in government-funded national mainstream schools or in special education ("SPED") schools. Approximately 26,000 students in mainstream schools are reported to have some form of special educational needs. However, this is based on the number of students who are accessing specialized services. The exact number of students with ASD in mainstream schools is currently not known. In order to support the inclusion of students with special educational needs in mainstream schools, the Ministry of Education (MOE) introduced the Support for Special Needs Initiative in 2005. As part of this effort, all primary and secondary schools are provided with Allied Educators – a learning and behavior support professional – who is trained in supporting the learning and behavioral needs of students with disabilities (such as dyslexia or other specific learning disorders as well as ASD in children without cognitive or verbal impairments) through direct and indirect approaches (i.e., in-class support and pull-out sessions for students, and/or training teachers). In addition, MOE has been providing in-service training to teachers to support students with special educational needs in mainstream schools. MOE is working towards equipping all teachers with baseline competencies to support students with SEN, and about 15% of teachers in every school have received training to equip them with deeper expertise in this area.

Complementing the educational services in mainstream schools are special education (SPED) schools for children who require higher levels of support. There are currently 19 government-funded SPED schools in Singapore, run by 12 Social Service Agencies (SSAs) serving approximately 6000 students. As mentioned, the provision of a

specialized ASD program within special education was first offered in 1989 at Margaret Drive Special School. Between 2004 and 2006, three SPED schools that provide specialized programs only for students with ASD diagnoses were established to meet rising demands in enrolment applications. These are the Pathlight School, the Eden School, and the St Andrew's Autism School. These schools complement the other SPED schools, most of which have ASD-specific programs or educational provisions for students with ASD. As part of the continual effort in enhancing accessibility to special education, more SPED schools are being established. Since 2018, three new ASD-specific SPED schools have begun operations, serving students with ASD with higher support needs, and another four ASD-specific SPED schools are planned from 2021 (Rajah 2019). There is considerable variation over the specific approaches or methods being implemented within the different SPED schools. However, some key characteristics that are shared include a customized structured curriculum, higher teacher-student ratio, collaboration with parents, specialized support from allied educational and health professionals, and a focus on developing communication, functional daily living, and social-emotional skills, with the aim of promoting life-long independence.

Specifically, the Pathlight School was set up by the Autism Resource Centre with government funding for school-going children with ASD who are able to access the mainstream National Curriculum with support, within a specialized learning environment. Apart from school-based education for its primary school students, the Pathlight School also offers a satellite school model for physical, social, and academic integration with mainstream school students for its secondary school students. Pathlight students attend school at the Satellite Partnership (Satellite Partnership program was introduced by the Ministry of Education to improve inclusivity and facilitate the interaction between students from SPED schools and students from 19 selected mainstream schools) mainstream schools daily (physical integration) and interact socially with their students

during recess and selected school events (social integration). Selected students, who have been assessed to be ready, join the mainstream classes for certain lessons (academic integration). This model provides for purposeful and meaningful, but gradual and individualized, participation in mainstream school and social integration.

SPED students in the other SPED schools also access meaningful participation and frequent interactions with their peers in mainstream schools, with the program targeted at vocational preparation, and transition to post-school independent living, learning, and working opportunities. The provision of Transition Planning Coordinators (TPCs) and Job Coaches to every SPED school, serving students aged 13 and above, supports the co-development and enactment of Individual Transition Plans together with the student, parents, and school personnel. The professional development for all staff, including that for TPCs, Job Coaches, and teachers, is funded by the government over and above the government's funding for all SPED school staff, operations, and infrastructure.

Services and Support for Adults with ASD

The exact number of adults with ASD in Singapore is currently not known, but based on an estimated rate of 1 in 167 Singaporeans having ASD, there are likely approximately 18,000 Singaporean adults with ASD (Tan 2011). However, only a small number of these individuals receive specialist support or training in adult centers. Similar to most other developed countries, it is increasingly being recognized that support and services for adults with ASD are very limited in Singapore. There is a current focus on the employment of adults with ASD. The Employability and Employment Centre (E2C) was established in 2012 to equip individuals with mild to moderate ASD with work skills and to support them in their efforts to secure and remain in employment. There is also a small but growing number of day activity centers providing specialized care for adults with ASD and intellectual disabilities, such as the St Andrew's Autism Centre, the Eden Centre for

Adults, and the Thye Hua Kwan Autism Centre. Aside from these ASD-specific initiatives, adults with ASD with comorbid intellectual disability can also access other day activity centers and sheltered workshops for individuals with intellectual disability.

Although adults with disabilities typically live with their families, some require residential support when their parents or family are unable to care for them (Poon 2013). Many autistic adults requiring residential facilities have typically been placed in homes for adults with intellectual disabilities. In 2018, the St Andrew's Adult Home, the first specialized residential facility with a capacity of 200 residents, began operations to meet the needs of adults with autism.

Research and Learning/Professional Development

Research

The first wave of research relating to ASD in Singapore in the 1990s and early 2000s focused on intervention approaches, including computer-aided interventions (Bernard-Opitz et al. 1999, 2001b, 2004; Chen and Bernard-Opitz 1993) and structured playgroups (Bernard-Opitz et al. 2004; Kok et al. 2002). Research in ASD in Singapore has grown considerably with strong collaborations forged between researchers from public organizations, clinicians, and leading academic institutions (i.e., National University of Singapore, NUS; National Institute of Education (NIE) at the Nanyang Technological University; Duke-NUS) to investigate a range of research areas and questions, including diagnosis (i.e., Sung et al. 2018; Wong and Koh 2016), early identification of children with ASD (i.e., Koh et al. 2014); early intervention (i.e., Poon and Bull 2016; Lim et al. 2007); the assessment of learning, functional level, and experiences of children with ASD in schools (Aljunied and Frederickson 2011; Aljunied and Frederickson 2013; Poon 2011; Poon et al. 2014); emotional and mental health comorbidity with a particular

focus on anxiety difficulties and psychopharmacology (i.e., Magiati et al. 2014, 2016; Ooi et al. 2011, 2014; Poon et al. 2014; Sung et al. 2010, 2011; Zainal et al. 2014; Zainal and Magiati 2019); the role and perspectives of families of individuals with ASD (i.e., Lai et al. 2015; Moh and Magiati 2012; Poon 2013; Poon et al. 2013a; Xue et al. 2014); the incorporation of technology in intervention and the role of screen time on behavioral difficulties (Cabibihan et al. 2013); the enlistment of autistic youth in National Service (Chay et al. 2020).

Training and Professional Development

In 2019, Singapore became the first Asian country to host the Asia Pacific Autism Congress (APAC) outside of Australia. This not only encapsulated the strong bilateral relationship between the two countries in terms of collaboration in research but also represented the maturity in research capabilities of the community in Singapore. The congress was organized by the Autism Resource Centre (Singapore) with the strong support from members of the Autism Network Singapore. The organizing and scientific committee members included partners from the local and international autism community including individuals on the autism spectrum. International and Asia-based speakers, autistic people and their families, researchers, educators, clinicians, and researchers shared their work and experiences in the congress. The conference theme “Thriving with Autism” (source: www.apac.autismcongress.org/2019/) aptly reflected the aspiration in research engagement towards maximizing the quality of life of all individuals with autism and their families in Singapore, and beyond.

Social Policy and Advocacy

Services for early intervention and special education are provided collaboratively between the government, VWOs, and the larger community, including corporations (i.e., “many helping hands” approach; Ho 2007). As such, volunteers play a large part in the service provision for

individuals with ASD in roles such as guidance in the VWO governance boards, assistance in organizing fund-raising and other events, and support in the day-to-day operations of various centers. The Autism Association of Singapore was established in 1992 by parents and currently operates two EIPIC centers, one special school and one Day Activity Center (DAC) for adults. Likewise, the Autism Resource Centre, established in 1999, has similar roots and currently operates an EIPIC center, a special school, the Employability and Employment Centre, an autism library, and an autism training and consultancy service that offers more than 2000 training seats per year. As from 2015, a small, but strong and growing, autistic community has emerged with several autistic adults taking leadership and advocacy roles and providing education, leadership, and much needed voices for autistic people in the country. Family members also feature prominently as advocates. For example, a parent who is also a journalist has published two collections of articles, one focusing on Singaporean families' perspectives and another on the independence of autistic adults, both with the aim of raising awareness of autism (Tan 2010, 2018). Parent advocates have also spearheaded various parent support groups in school communities, via online platforms and through social media.

Disability support offices (DSOs) have been established in publicly funded institutes of higher learning (institutes of higher learning in Singapore includes universities, polytechnics, the Institute of Technical Education, private education, and the arts institutions, under the purview of the Division of Higher Education Group of the Ministry of Education) since 2014 to support students with special needs, with services expanded to cater for an increasing number of autistic students entering these higher learning institutions. Institutes of higher learning have also incorporated modules specific to autism, such as for psychology undergraduates at the National University of Singapore and for educators at the National Institute of Education.

Current Issues and Future Directions

Notwithstanding the country's brief history, there has been considerable effort to develop services and supportive infrastructures for individuals with disabilities, including those with ASD, and their families. Although considerable progress has been made, there continues to be a number of areas for further growth. There is a need to further raise the bar for the quality of services for school-aged children, adolescents, and undiagnosed adults with ASD. With increasing numbers of students with ASD accessing the mainstream education system, there is a pressing need to improve on the inclusion and support for these individuals, including looking at ways to diversify the continuum of provisions available to students with ASD (Enabling Masterplan 2007). Caregivers and families continue to report long wait times, particularly for post-school services. More resources need to be injected to develop more and better quality services to support those in higher institutes of learning (such as the polytechnics and universities), those in the workplace, and those who may not be suitable for independent employment. More services need to be developed in the areas of diagnostic services in the adult population and in mental health and emotional support services throughout the life-span for the autistic individuals.

There is also a need to further align and synergize the efforts of schools, professionals, researchers, and other service providers in order to maximize the potential of the individuals with ASD and to enhance their quality of life. While the number of services and centers has increased considerably, the quality and impact of intervention and educational approaches remain under-evaluated. Few programs can clearly document the empirical evidence on which their development and implementation are based, with the exception of the structured teaching approach, which appears to be a component shared across most intervention settings. For this reason, there have been government-initiated and government-funded efforts to improve and standardize the

quality of early intervention services offered. These efforts have taken the form of a study to describe the state of services (i.e., EIPIC baseline study), a consultancy service to improve the quality of services (i.e., EIPIC Consultancy Project), and an ongoing evaluation study to systematically measure the outcomes in addition to the child, family, and intervention factors associated with the progress of the children receiving EIPIC interventions.

Separately, the Autism Resource Centre's Early Intervention Programme has embarked on an international accreditation by the United Kingdom's National Autistic Society, which provides a rigorous quality assurance service to autism-focused programs around the world. Finally, another area for development that has been highlighted includes providing greater support for the autistic individuals during transition phases across the developmental life-span (e.g., Poon and Lim 2012; EM Steering Committee 2012). To address this, a number of programs are currently in progress, such as a project seeking to support the transition of children with ASD from preschool to primary schools, as well as a hospital-based early intervention program for caregivers of recently diagnosed children with ASD (Temasek Cares 2013). One of the restructured hospitals, KKH, has initiated a home-based program for children with ASD and their families (SAFE; Support for Autism through Family Empowerment), which aims to provide families of newly diagnosed children with the knowledge of ASD, information on available services, and parenting/management strategies (Lim, personal communication).

The national approach spearheaded by the Enabling Masterplans has good potential to continue to set directions for the management and coordination of services, and the autism-specific Masterplan currently being developed will likely put autism more firmly and specifically on the national agenda, bringing about pertinent and sustainable improvements in the next 10 years. It is important that the voices and needs of the individuals with ASD and their families take a central

place in the implementation of the agenda set by the Enabling and Autism Masterplans. Finally, to ensure that the understanding of the needs of this population is current and robust, there is an increasing need to further continue to promote collaborations between autistic people, their families, schools, professionals, and researchers.
